Physical Society, May 25.—The President, Prof. W. G. Adams, in the chair.—The following candidates were elected Members of the Society:—W. Kieser, T. McEniry, W. R. Philips, G. M. Whipple.—Mr. D. J. Blaikley read a paper on brass wind instruments as resonators, describing an attempt he has made to carry into some detail certain acoustical investigations of the late Sir C. Wheatstone. A method by which the positions of the notal points in a cone and in a bugle had been fixed was shown, and it was then shown that a complete cone cannot be used by the lips as a wind instrument, that conic frustra cannot give resonance to the same series of notes as complete cones, and that therefore the conical form must be modified; and, as this modification of form makes the position of a node for every note required more or less coincide with that of the lips, so will the instrument be more or less perfectly in tune. As the number of quarter wave-lengths in a cone or wind instrument is not directly proportional to the vibrational number of the note, as it is in free space or in an open tube, so the velocity of the wave of a given note is not exactly the same as that of another note of different pitch. Experiments were shown to illustrate the effect of varieties of form in producing different qualities of tone, and evidence was given of the existence of very high harmonic or partial tones in the low notes of wind instruments. In the trombone the ninth partial tone (three octaves and a tone above its prime) was thus proved to be sounding, and partial tones up to the sixteenth have been heard.—Sir W. Thomson pointed out the connection between the range of a musical instrument and the phenomena observed in a trumpet-shaped bay between high and low water; he also considered that an investigation of the overtones due to the cavity of the mouth would well repay research in explaining the influence its shape has on the vowel sounds.—Lord Rayleigh observed that in a conical musical instrument, the correction to be made on account of the cone not being perfect to the apex is equal to six-tenths of the radius of the open end, and he pointed out that with a bell-mouthed instrument much of the sound is diffused as spherical waves.—Dr. Guthrie placed on the table a communication on salt solutions and attached water and on the separation of water from crystalline solids in currents of dry air, in continuation of his researches, which have already been published. The results could not be usefully abstracted, but as an instance of the important results obtained it may be mentioned that Dr. Guthrie finds that when dry air is passed over chloride of barium at a temperature just above 25° C., the β molecule of water is given off, and that the α molecule of water is only separated at a temperature just above 60° C. He also showed the effect of a steam jet in boring through a block, mainly with a view of obtaining suggestions as to the use of such a method in the commercial preparation of ice.—Mr. Rutherfurd then showed a photograph of the solar spectrum from the line E to H, taken by means of a grating. By means of a heliostat he concentrated the rays on a lens within a collimator, which in relation to the observing telescope was of considerable length, in order to admit as much light as possible, and the grating was movable. The enlargement was effected by inserting a lens near the focal point of the observing telescope, and he used a sensitive collodion which gave the greatest sharpness of definition about the line G.—Sir W. Thomson, in continuation of the communication made to the Society at its last meeting, described the effect of torsion on the electric conductivity of a tube of brass. We have already given an account of this paper.

Anthropological Institute, May 28.—Major-Gen. A. Lane Fox, F.R.S., vice-president, in the chair.—Mr. Hyde Clarke exhibited a carved stone object which was considered as having come from Central America.—Col. Paske read a paper on Buddhism in Little Tibet. After a brief description of the route through the Kangra and Kulu Valleys to the high mountain passes leading into Lahore and Spiti, he gave particulars of the physical features of these countries, their products, &c., with some account of the habits and customs of the people, concluding with observations on Buddhism. Col. Paske gave an explanation of the modified form of Buddhism prevalent in the provinces of Little Tibet, and brought to notice the ritual and religious customs of the Lamas or Buddhist priests; described his visits to Buddhist monasteries, exhibiting specimens of Buddhist ritualistic instruments, and other curiosities, with a small painting representing the "Triumph of Buddhism," executed by a Lama recently arrived from Llassa.—Mr. Brabrook read a paper by Mr. Alfred Simson, entitled Notes on the Piojés of the Putumayo. A tribe of Indians occupying the middle and lower Aguarico and a considerable stretch of the left bank of the Napo are known as the Santa Maria Indians or Piojés, from the word in their language, piojé, and speak the same language, and have several traits in common with the Indians inhabiting the borders of the Upper Putumayo, who seem to have no special appellation, but which Mr. Simson proposed to call the Macaguajes or Piojés of the Putumayo. Mr. Simson's experience of these Indians extended only to those living on the banks of the main stream, during long journeys with a number of them selected from different villages, and visits and sojourns in most of these villages. Their dwellings, religion, and customs were freely described. Mr. Simson also communicated a vocabulary of the Zaparo language.

Geological Society, June 5.—John Evans, F.R.S., vice-president, in the chair.—William Santo Crimp and Joseph Richard Haines were elected Fellows of the Society.—The following communications were read:—On the quartzites of Shropshire, by Charles Callaway, F.G.S.—On the affinities of the Mosasauridæ, Gervais, as exemplified in the bony structure of the fore fin, by Prof. Owen, C.B., F.R.S.—On new species of *Procolophon* from the Cape Colony, preserved in Dr. Grierson's museum, Thornhill, Dumfriesshire; with some remarks on the affinities of the genus, by Harry Govier Seeley, F.L.S., Professor of Geography in King's College, London.—On the microscopic structure of the Stromatoporidæ, and on palæozoic fossils mineralised with silicates, in illustration of eozoon, by Principal Dawson, F.R.S.—On some Devonian Stromatoporidæ, by A. Champernowne, F.G.S.—On a new species of *Loftusia* from British Columbia, by George M. Dawson, F.G.S., of the Geological Survey of Canada.

Chemical Society, June 6.—Dr. Gladstone, president, in the chair.—The following papers were read:—Analogies between the action of the copper-zinc couple and occluded and nascent hydrogen, by Dr. Gladstone and Mr. Tribe. The authors have observed that finely-divided copper charged with hydrogen converts nitre into potassium nitrite and ammonia, and reduces potassium chlorate to chloride. The copper-zinc couple converts nitrobenzol in aqueous solution into anilin, a reaction which the authors have utilised for the detection of small quantities of nitrobenzol. The action of palladium-hydrogen, platinum-hydrogen, and carbon-hydrogen on various substances have been investigated, and compared with the action of the copper-zinc couple. During the reading of the paper, Dr. Russell took the chair.—On the alkaloids of the aconites, Part 3, by Dr. Wright and A. P. Luff. The authors have continued their researches on these alkaloids, and in the present paper investigate the saponification, &c., of aconitin, picraconitin, and have obtained two new bases, aconine and picraconin; acteyl and ben-

zoyl derivatives of several of the bases have been formed. The authors draw an important practical conclusion from their work, that it is quite possible to obtain crystallised alkaloids of constant composition from *A. ferox* and *A. napellu*, instead of the amorphous preparations which are now sold, and which often contain forty or even ninety per cent. of bases more or less inert.—On the alkaloids of the Veratrums; Part 1, Alkaloids of *Veratrum sabadilla*, by Dr. Wright and Mr. Luff. After discussing the conflicting statements which have been made by previous observers, the authors give details of the process of extraction, which consisted in percolating the crushed seeds with alcoholic tartaric acid, evaporation and extraction by numerous and prolonged shakings with ether. Three alkaloids were obtained: veratrine, $C_{37}H_{53}NO_{11}$, which, on saponification, splits up into veratric acid, and a new base, verin; cevadin, $C_{32}H_{49}NO_9$, splitting up, on saponification, into cevadic acid (methylcrotonic acid) and cevin; cevadillin, $C_{34}H_{53}NO_8$, which does not crystallise or form crystalline salts.—On the action of hydrochloric acid upon chemical compounds, by J. W. Thomas. The author has examined the action in several ways of hydrochloric acid on many salts, nitrates, sulphates, tartrates, citrates, chromates, oxalates, &c.—On the action of oxides on salts, Part 1, by Dr. Mills and Mr. Wilson. The object of the authors was to determine the law in consequence of which the action of oxides on salts leads in general to the formation of other oxides derived from the salts in question. They have studied the action of tungstic, silicic, and titanic oxides on potassic carbonate at a high temperature.—On a new test for glycerin, by Dr. Senier and Mr. Lowe. This test is founded on an observation of Iles, that borax, when treated with glycerin, gives to a Bunsen flame the green colour characteristic of boracic acid. By means of the test, one-tenth per cent. of glycerin, was detected in beer after concentration, &c.—On ammonium triiodide, by G. S. Johnson. The author has prepared this substance by dissolving iodine to saturation in a strong aqueous solution of ammonium iodide, and by stirring crystals of ammonium iodide and iodine with a small quantity of water, till the resulting black liquid refused to dissolve more of either ingredient. The liquid, on evaporation over sulphuric acid, gave dark blue prisms of the substance in question slightly deliquescent; specific gravity, 3·749.

PARIS

Academy of Sciences, June 24.—M. Fizeau in the chair.—The following among other papers were read:—On the displacement of the bubble in spirit-levels, by M. Plantamour. Movements were observed (both from day to day and in the course of single days) in levels placed on the massive table of the author's limnograph, at Geneva, on the beton covered ground beside it, on the ground in a tent, and also in the author's cellar, some distance from the lake. In certain periods there is a gradual rising in the east without notable return to the west; in others there is a certain horizontal immobility, and in others, lastly, of longer or shorter time, the ground undergoes oscillations both from east to west and from north to south, more or less pronounced and regular, the limits being, however, always narrow (the greatest movements did not reach twenty seconds). M. Plantamour does not at present try to explain these movements; (they are indicated graphically).—M. D'Abbadie recalled similar observations he had formerly made, and thought this phenomenon might be an important source of error in astronomical calculations (*e.g.*, in determining latitudes and the declination of stars).—M. de Lesseps presented a stone from Chalouf, 10m. above the sea, believed to belong to the tertiary epoch, and having incrusted on it a large shark's tooth, three times the size of teeth of sharks now caught in the Red Sea, and probably belonging to a species now gone.—The death of M. Ehrman, correspondent at Strasburg, was announced.—Results of application of sulphocarbonate of potassium to phylloxerised vines, by M. De la Vergne. He considers it indispensable for very young plants with small root system, and for all vines grown in a very thin layer of mould.—On the depolarisation of electrodes by solutions, by M. Lippmann. The property of depolarising a metal belongs exclusively to salts of that metal. Hence a method of detecting the presence of a particular metal in a solution. Thus, for copper; put a copper wire as negative electrode of a weak current in the liquid; it will be polarised if there is no copper dissolved in the latter, and it will not be polarised if the liquid contain $\frac{1}{5000}$ of sulphate of copper. For silver the sensibility seems to be greater.—On a new dielectric constant, by M. Neyreneuf. In comparing different dielectrics in a condenser, he finds that for glass of the same nature the ratio $\frac{e}{n}$, of the thickness to the number of sparks corresponding to a given quantity of electricity, is constant. For more insulating substances, as ebonite, caoutchouc, &c., this ratio or *condensing constant* increases considerably with the thickness; the condensing constant of air is much greater. There is no similarity between the condensing constant and the ordinary dielectric constant.—On an experiment in magnetism relative to the telephone, by M. Luvini. He filled a hollow electromagnet with water which he inclosed, a capillary tube being connected to show any variations in the capacity; but no such variations appeared with any kind of current. (The arangement would have indicated a change of volume of $\frac{1}{30}$ cub. mm.) He infers that the changes caused by magnetising action in a magnetic mass are wholly molecular. The sounds in resonant electro-magnetic rods discovered by Page are due to reactions of the two magnetic movements, and the current.—On the telepone, by M. Des Portes. This relates to experiments on board the *Desaix*; a telephone being at one end of the circuit and a telephone magnet, with coil uppermost, suspended vertically by silk thread. The latter magnet was struck with various substances, wood, soft iron, &c., and the sounds were heard. Peculiar effects were got on striking with a magnet or speaking. M. du Moncel added an account of similar experiments.—On electro-magnets, by M. Bisson. He winds in a new way: after each row he brings the wire in a straight line to the starting-point and recommences. He thus obtains a third more power.—On the efficacy of a vibratory movement for causing decomposition of explosive liquids and ebullition of superheated liquids, by M. Gernez. He rubs the tubes with a wet cloth, producing vibration and sound.—On organic dust in suspension in the air, by M. Miquel. The average number of microbes of the air, small in winter, increases rapidly in spring, remains nearly stationary in summer, and diminishes in autumn. Rain always causes their recrudescence.—On the pressure of the cephalo-rachidian liquid, by M. Bochefontaine.

CONTENTS

ERRATA.—Vol. xviii. p. 215, 1st col., 33rd line from bottom, for "sea" read "Lea." P. 216, 2nd col., 15th line from top, for "489 mm" read "4 mm. square."

THURSDAY, JULY 11, 1878

SCIENCE IN SCHOOLS

WE print with pleasure on another page a remarkable article from the *Times* of Monday. In itself the article may present nothing remarkable to the readers of NATURE, but as the deliberate utterance of the leading organ of opinion in this country, it marks a distinct stage of progress towards a more enlightened conception of what constitutes education. We hope that it is significant of the near approach of a radical change of the conception in this country of what subjects should be included in elementary education. We need not be surprised at the fate of Sir John Lubbock's Bill for the introduction of elementary science into schools, when such erroneous conceptions of what science is apparently exist in the mind of the Minister of Education in the House of Commons, Lord George Hamilton. The Vice-President of the Council has much to learn, when his idea of the Royal Society, one of the most venerable institutions in the country, is that of a kind of select Polytechnic, where "lectures" are delivered on "biology, chemistry, natural history, mechanics, astronomy, mathematics, and botany." But he is new to his work, and we must hope that the debate of Thursday last may lead him to obtain a more accurate conception of what is meant by elementary science.

Dr. Lyon Playfair, we believe, pointed out what is one of the great hindrances to the introduction of science into elementary schools; the mere name, "science," frightens ministers, inspectors, school-boards, and teachers; perhaps if the simpler phrase, "elementary knowledge," were used, the simple-minded individuals in whose hands are the training of our future citizens might find that they themselves had been compelled to become acquainted with it to their cost after they left school, and that it would have been much better for them had they had some little training in it before entering into the thick of the fight.

The most notable feature in the *Times* article, as well as in Thursday's debate, is the fact that it has at last dawned upon the leaders of opinion and the makers of our laws, that "education" and "instruction" are different things, and that a man may learn a great many "facts" at school, and have his education to begin when he leaves it. It is lamentable that we have to be continually reminded that we are the only one of the great European countries where this distinction is not recognised and practically carried out in education. Our whole system of education, hitherto, has been a mere cramming of the children's memories with words, words, words, to the weariness of children and teachers, and with results unsatisfactory to all concerned. As the *Times* puts it:—"To be taught something about gravitation, about atmospheric pressure, about the effects of temperature, and other simple matters of like kind, which would admit of experimental illustration, and which would call upon the learner to make statements in his own words instead of in those of somebody else, would be so many steps towards real mental development." Sir John Lubbock gave a most conclusive refutation of the idea that the teaching of science must be attended with hitherto unexperienced difficulties, and at the same time proved what a relief science-teaching would be to the ordinary dull routine of instruction, when he told the House that in the Scotch schools the authorities began to take alarm because science-teaching was found so comparatively easy and pleasant by the children. As to the argument that children who have been taught to know something about the objects and forces with which they every day come into contact contract a distaste for manual labour, we should have thought it had been long ago played out; it has almost as much force as the story told by another speaker of the boy who had been impudent to his master because the latter could not read his newspaper.

It is unnecessary for us to go again into the merits of the question which has been so often and so thoroughly discussed in these pages, especially as the *Times* has put it quite as forcibly as there is occasion for doing at present. It certainly seems sad, nationally suicidal, indeed, that a few more millions of those who will have the destinies of this country in their hands, are likely to be launched into active life, with all their education to acquire, ere legislation steps in to give us the advantages which nearly every other civilised nation gives to its children. Every day we hear of the ignorance of the working classes, every other month "congresses" are held to devise means to remedy the consequences of this ignorance—ignorance of the laws of health, ignorance of household economy, ignorance of the implements and objects of labour, ignorance of the laws of labour and production, ignorance of the nature of the commonest objects with which they come into contact every day, ignorance of almost everything which it would be useful and nationally beneficial for them to know—an ignorance, alas! more or less shared by the "curled darlings" of the nation. Yet while every day's paper shows how keen is the industrial competition with other nations, and how in one department after another we are being outstripped by the results of better—*i.e.*, more scientific—knowledge, the poor pittance of "elementary knowledge" asked for in Sir John Lubbock's Bill is refused by a minister whose own "education" leaves much to be desired. This state of things cannot long continue, and with such advocates for the children as the *Times* and Mr. Forster, we may hope that next time Sir John Lubbock brings forward his Bill it will meet with a happier fate.

THE JUBILEE OF UNIVERSITY COLLEGE

LORD GRANVILLE'S admirably reasoned and temperate speech at the jubilee of University College on Tuesday, reminds us how things move in this country. It records half a dozen great advances which are now accepted cordially and universally, with all of which University College is more or less identified, and in promoting which it has never failed to take a leading part.

To begin with, there is the absolute catholicity of its offer to the student—the invitation on its motto is *Cuncti adsint, meritæque expectent præmia palmæ.* When the University

of London began in 1828, and when University College was incorporated in 1836, Oxford and Cambridge had not dreamt of throwing open their doors to dissenters. To-day the whole world so absolutely recognises the propriety of the step which University College then took, that it is difficult to give it enough credit for a courage which was then without precedent in England. Only the other day its invitation has been widened still farther. *Cuncti adsint* is to be understood as including *Cunctæ adsint*, and women as well as men will henceforth have unrestricted access to the classes in the faculties of arts, law, and science. Women are at least as much influenced in character by the kind of education which is given them as men are, and the action of University College guarantees that women—in London, at least—will have at their disposal the best education which England can offer.

The Chancellor of the University of London reminded us that the new demands of teachers of science have compelled institutions like University College to extend their buildings and to provide laboratory facilities in addition to the class-rooms and lectures of old days. University College is not alone in recognising this vital fact. King's College has thoroughly developed its practical teaching; the Scotch Universities have latterly been very much alive on the subject; Owens College, as becomes a new institution claiming to take rank with the most advanced teaching bodies of the day, has given exceptional prominence to laboratory work. But University College has not been unconscious of the movement, and she purposes, if possible, to outstrip her rivals.

The last movement, in which Lord Granville reminds us that her action has counted for a great deal, is that to extend the English definition of a university. She considers herself entitled to that appellation. "Now the term 'University,'" says Lord Granville, "has been differently understood by different persons and by different nations, and I think that the exact construction of it is very likely to be still more minutely debated in consequence of the able efforts of one of the most distinguished students of your college, now the most successful president of Owens College, whom we see among us, who has raised the question whether the number of universities ought not to be increased. In France 'university' means an aggregrate of all the schools and colleges of the kingdom. In Germany their famous universities are really professorial schools. Our two elder universities are really academical institutions—an aggregate of colleges. You know that the London University is not a teaching body at all, and that it is only an examining body, depending upon other sources, of which this college is the most prolific in giving us candidates for our examinations." The institution of University College has done much, the movement of Owens College has done more, to widen our ideas of what a University might do. There is no reason why we should be confined to the existing type of "academical institutions—an aggregate of colleges," supplemented by an examining body depending on other sources. We do not aim at French centralisation, but there is no reason why one or two universities on the German or the Scotch model should not be added to the very limited list of our English Universities. An amalgamation of University College and King's College into a teaching University of London would be a natural consequence of such a movement.

WINDMILLS AND WATERFALLS

OUR readers may remember the consternation caused some years ago by the publication of Prof. Jevons's work on our coal supplies, and the alarmed inference drawn from his calculations that the days of Britain's supremacy and prosperity were numbered. Certainly, if our prosperity is entirely dependent on our coal supplies, there can be no doubt that ere very long the beginning of the end will have arrived. Abundant as our coal supplies are their consumption at the rate of about 150 million tons annually cannot go on for ever; and while we may have the ships and the money too, it would be a serious thing for England if she had to look abroad for her greatest source of physical power. It is certainly at present difficult to see how the work of the world could be carried on if the supply of coal were completely exhausted; still if man were compelled to find a substitute or relapse into savagery or even perish altogether, we think the chances are he would be able in some way, without detriment to his progress, to adapt himself to his new circumstances. These ideas have been suggested by an interesting lecture, just published, recently delivered at Glasgow by Dr. C. W. Siemens, "On the Utilisation of Heat and other Natural Forces."

"The supremacy," he justly says, "which man enjoys over the animate and inanimate creation, and for which Divine Authority may be quoted, cannot be said to be the result of his superior muscular development, for amongst the members of the animal kingdom there are many which are his superiors in strength, agility, swiftness, and in natural aptitude to provide themselves against the vicissitudes of cold and hunger. The compensating advantage in our favour is the intelligence with which we are enabled to call forces of nature not our own into requisition to do our behests. It would not be too much to say that the power of man consists really in his ability to direct the forces of nature, and that the degree of civilisation to which he has attained is commensurate with his command of those forces."

Could any more forcible argument be urged in favour of the national advantages of scientific research, or of the yearly increasing importance of scientific knowledge in the every-day life of humanity?

Fortunately Dr. Siemens, in his lecture, gives us a pretty wide glimpse of hope that we need not despair because of the prospective exhaustion of the existing means of producing utilisable heat. Other methods, he suggests, might be found of bringing into action this greatest source of mechanical power, and that even now one of these methods might be so used that the exhaustion of our coal might be postponed for a considerably longer period than has been calculated. Dr. Siemens traces the progress of our knowledge of the real nature of heat and of the methods of ascertaining its mechanical equivalent. He shows how gradually we have learned to produce a greater and greater amount of mechanical effect from the

consumption of a certain quantity of heat in the steam-engine, the blast-furnace, and other methods of utilising this source of power as derived from coal, and points out how, by means of electricity, this agent may be made to do a greater amount of work for us than ever. The wonderful results obtained from the Siemens' dynamo-electric machine are well known, and Dr. Siemens gives an example of the saving of power that might be effected by its use:—

"Let us suppose that at some central station 100 horse-power of steam or water power was employed to give motion to several dynamo-electric machines of the dimensions found most convenient in practice, and that by means of metallic conductors of suitable dimensions the electric current produced at the central station was conducted to a number of halls or factories requiring to be lighted, or to utilise mechanical power. If illumination were the only object in view, the total amount of light that could be thus produced would be equal to 125,000 candle-power. This would be equivalent to 6,250 Argand burners, each of 20 candle-power, at a consumption per burner of 6 cubic feet of gas per hour, or a total consumption of 37,500 cubic feet of gas to produce the same effect of light. This would require 3¾ tons of coal, and the electric light about as many hundredweights."

Now if the power to drive these machines could be obtained apart from coal the addition to our mechanical resources would be immense. While Dr. Siemens shows that the tides are a source of power that might be utilised directly or indirectly, he at the same time shows that the results would not be at all commensurate to the work expended. But the old sources of power, which have gradually given way before the universal introduction of steam—wind and falling water—might again be called into play, and with infinitely greater effect than ever. It is evident that within certain limits the rotatory motion required for the working of the dynamo-electric machine might be effected by means of the old-fashioned windmill, and to a much greater extent by means of falling water. Our readers may remember that Dr. Siemens, some months ago, in an address which he then gave, referred to the immense quantity of power which flowed ready made over the Falls of Niagara. In his Glasgow address he again referred to the subject, in order to show how this gigantic source of power might be utilised to produce action at a distance. "When," he says, "little more than a twelvemonth ago I visited the great Falls of Niagara, I was particularly struck with the extraordinary amount of force which is lost, as far as the useful purposes of man are concerned. 100,000,000 of tons of water fall there every hour from a vertical height of 150 feet, which represent an aggregate of 16,800,000 horse-power, producing as their effect no other result than to raise the temperature of the water at the foot of the fall

$$\frac{150}{772} = \frac{1^\circ}{5^\circ} \text{ Fahr.}$$

In order to reproduce the power of 16,800,000 horses, or, in other words, to pump back the water from below to above the fall, would require an annual expenditure of not less than 266,000,000 of tons of coal, calculated at an average consumption of 4 lbs. of coal per horse-power per hour: which amount is equivalent to the total coal consumption of the world. In stating these facts in my inaugural address on assuming the presidency of the Iron and Steel Institute, I ventured to express the opinion that in order to utilise natural forces of this description at distant towns and centres of industry the electric conductor might be resorted to. This view was at that time unsupported by experimental data such as I have been able since then to collect." Dr. Siemens then shows what has been done in conveying the electric light to a distance; and he points out that, "if mechanical force is required to be distributed, the arrangements are in every respect similar to those for the distribution of electric light; and it has been proved experimentally that the amount of power recovered at the distant station is nearly equal to half the power employed at the central station." Even as regards the consumption of coal, were that article used, Dr. Siemens shows that the magneto-electric machine is cheaper than the gas or steam-engine. But he rightly says:—"It would not be necessary to seek on the other side of the Atlantic for an application of this mode of transmitting the natural force of falling water, as there is perhaps no country where this force abounds to a greater extent than on the west coast of Scotland, with its elevated lands and heavy rainfalls. You have already conducted the water of one of your high-level lochs to Glasgow by means of a gigantic tube; and how much easier would it be to pass the water in its descent from elevated lands through turbines, and to transmit the vast amount of force that might thus be collected, by means of stout metallic conductors, to towns and villages for the supply of light and mechanical power!"

Dr. Siemens points out other directions in which the natural forces of the universe might be used for the purposes of man, without resorting, to such an extent as we do at present, to our coal supplies. While windmills are directly rather an uncertain source of power, still, he shows that a number of windmills, such as may be constantly seen working in Holland for the drainage of the land, might, for instance, be employed to raise water, by pumping, to an elevated lake or reservoir, whence the power could be drawn off by means of hydraulic motors when required, and might be conducted electrically to centres of habitation.

We ought to be grateful to Dr. Siemens for taking so much pains to lighten up the gloomy prospects which some pessimists have been presenting to us for some years past; and to those who may be cynical enough to reply that a return to the windmill and the water-wheel is simply a sign of the prophesied retrogression, we may fitly reply, in Dr. Siemens' own words:—

"It would be wrong to suppose that a resumption ot the use of natural forces would throw us back to the time of the windmill and the primitive water-wheel which used to give motion to isolated establishments. We shall have learned to store, to transport, and to utilise these forces in a manner adapted to our superior requirements; and who knows whether the time may not come when our descendants in the third or fourth generation will look back upon the indiscrimate users of coal with something like the same feeling that we look upon the users of flint and bronze implements. Indeed, without waiting for the extinction of our coal-fields, it

appears to me not improbable that natural forces will be resorted to simply on account of their comparative cheapness and convenience of application."

WEST YORKSHIRE

West Yorkshire: an Account of its Geology, Physical Geography, Climatology, and Botany. Part I.—Geology. By J. W. Davis, F.G.S., F.L.S. *Part II.—Physical Geography and Botanical Topography.* By J. W. Davis and F. Arnold Lees, F.L.S. With Maps and Plates. (L. Reeve and Co., 1878.)

THE merit of a work on local geology or natural history may be of two distinct kinds. The author may be an original investigator of a little-known area, and his book a positive addition to our knowledge; or the volume may be a tapestry, into which the scattered threads of information are worked by one who has the mastery of them all, and who presents us with the picture they have formed in his mind. It is to excellence of this latter kind the authors of "West Yorkshire" aspire. They have gathered from the contributions of all local observers, and have so assimilated the material with their own knowledge, as to render the substance of their book a useful outline of the geology and botany of the district they have chosen to illustrate. An area included within the region of Prof. Phillips's classical work on the mountain limestone districts of Yorkshire, and upon whose coal-bearing and associated strata so much good work has been done by the Government Survey, does not leave much room for novelty in its geology, though the botany, especially as treated in this book, is in rather a different case. The great merit of the work would therefore consist in the lucid and comprehensive manner in which it presents the scattered information to us as a whole. This, however, it scarcely possesses in as great a degree as most of the books of its class.

Examined in detail there are some points which call for remark. The introductory chapter is mostly occupied with a description of the boundary line of the riding—a most uninteresting subject—but it is enlivened by the accounts of the Pennine and Craven faults. The drawing of the latter, however, on the maps does not coincide with the description, and the former is scarcely indicated. This map —a most excellent one and derived from the best sources —unfortunately contains one or two other errors, viz., the Ingleton coal-field is wrongly coloured, and the words "upper Silurian" and "lower Silurian" are mismatched in the "references." In the next chapter the small Silurian area is well though shortly described, and we are then very admirably shown that the red conglomerates at the base of the mountain limestone in some places are the shore deposits of the early part of the latter epoch. The *pièce de résistance*, however, of this portion of the book is naturally the chapter which treats on the Carboniferous period, in which also are to be found the chief novelties due to the author. The lie and position of the great masses which form the backbone of the country are admirably given, and all the lately acquired information is incorporated. The lists of fossils, however, from the lower rocks, do not seem to have undergone much critical revision, and remarkably few additions seem to be recorded during the last thirty years. It is interesting to notice that, with respect to the lower coal measures, the author states his conviction that "the tendency of all the evidence in this part of the country is to show that the Gannister series and the Millstone grits form one natural division of the Carboniferous system," though he does not go so far as Prof. Hull in classifying them together. A valuable feature here is a set of comparative sections in different districts in which the locally-named coal beds are correlated, and which gives a very good idea of their changes. Some of the most interesting features of the Yorkshire coals, however, such as the convergence of many seams into the Beeston coal and the peculiar character of the Better bed coal, though mentioned, are scarcely made enough of, but the fossils associated with the latter have been very well worked at. The proof of the unconformity of the permian limestones and the true age of the picturesque Plimpton rocks, once associated with them, is admirably given, and then this part of the work concludes with an account of the superficial deposits, glacial striæ, and the Victoria Cave.

The second part, which, according to the preface, is only the introductory chapter to the complete flora of the Riding, to be produced in another volume, is more interestingly written. The area under consideration is divided into ten districts indicated on a map, and coinciding with the drainage areas. In each of these the relation of the flora to the general physical characters is pointed out, and lists of the most interesting plants found in selected and naturally separate localities are given, accompanied by remarks on the surrounding country. In each we are taken to the head sources of the river which runs through the district, and so pleasantly are we led along its banks that we seem to realise the several beauties of the neighbourhood while we learn their cause, and to collect all the interesting plants whose habitats are so graphically described. Great care seems to have been taken to exclude all doubtful statements, and to show the cause of the occurrence of particular sets of plants, where this is possible. It is therefore thoroughly reliable, and from the scattered nature of the little that had previously been done, contains more new matter than is to be found in the first part.

The book is accompanied by sixteen plates of geological woodcuts, which are rough, and add but little to its value. There are also five plates of coloured sections, mostly founded on those of the Survey.

We must certainly congratulate the authors on the completion of their task, which has been carried out in a creditable manner, and has resulted in a useful and instructive book.

OUR BOOK SHELF

Flowers. By J. E. Taylor. (Hardwicke and Bogue.)

THIS is a compilation in small octavo, illustrated with many familiar woodcuts and coloured plates. A feature is the index of 1,000 references. Very many of these, being only to the merest mention of names, might have been omitted in favour of a glossary of terms, and more especially a list of works of reference.

The principal aim throughout the book is to convey that all the many adaptations of flowers to secure fertilisation are due to a Divine Creator, and not thought out by the plants themselves. The theory of Natural Selection is hardly alluded to.

In glancing through the geological portion errors of fact, such as that palms are oolitic, are seen to be numerous. The confidence too with which the exact succession of dicotyledons in geological time is set out is not warranted by the present state of our knowledge. We read the oft-repeated theory, now stated as fact, that *Apetalæ* preceded *Polypetalæ*, and these *Gamopetalæ*. That this succession really took place, however probable in itself, is, it is well known, far from proved. The actual flowers discovered in the lowest eocene—almost the oldest dicotyledonous flowers known—are *Gamopetalous*, and have been referred to *Porana* and *Symplocos*. The abundance and differentiation of the *Papilionaceæ*, the *Cæsalpinaceæ*, and the *Mimosæ*, show how ancient are the *Polypetalæ*. Any preponderance we may fancy the wind-fertilised *Apetalæ* possess is due to the fact that most of them are forest trees, and it is the leaves of these which form the great mass of the known dicotyledonous floras. Were those divisions really produced in the sequence assigned them, the origin of all alike is far older than the eocene and at present unknown to us: so that even thus the writer of the book is in error.

A most unfortunate selection of illustrative genera of eocene plants has been made. Azaleas did not abound in the eocene, and have never even been met with in it. Neither did the cactus nor aroids, since they have been but recently noticed in the eocene, and then only in England. In like manner the "peculiar" feature attributed to the miocene, its gathering together in the same flora plants now only found at immense distances apart, is not a peculiarity of that formation, since it characterises eocene floras in at least an equal degree. Chapter IV., on the geographical distribution of flowers, deserves especial mention, but must be consulted itself should any one desire to learn (p. 80) how "the *Proteaceæ* became Australian, the magnolias and tulip-trees chiefly North American."

Looking at the more botanical part of the book, it is seen that the explanations of the modifications and appliances of flowers to insure fertilisation are in some cases not treated with the caution the subject requires. To select an instance: the theory that white flowers open more than any others at night, because they are the most visible to moths, seems probable at first sight; but the unscientific reader, to whom the work is addressed, wishing to see for himself, would reject it after his first walk down a hedgerow at eventide, when he found the dog-rose, the white convolvulus, and the daisy, all closed. Why, too, white flowers, if they rely upon their colour to attract, should be also the most powerfully scented, is not explained. It is likely that perfumes would be more necessary to the dark-coloured flowers which are open at night, unless we suppose, which from experience we of course should not, that only white flowers are fertilised by night-flying moths. Persons whose experience of flowers is confined to ordinary English gardens would remember the heliotrope, the mignonette, musk, yellow azalea, wall-flower, rose, coloured pink, hyacinth, violet, scented verbena, scented geraniums, as the most highly-perfumed plants, and would reasonably doubt that any exceptional attractions in this respect belong to white flowers. In comparison with perfume, the white colour may have little to do with it, but Mr. Taylor must have remarked that some law gives vastly superior brilliance to butterflies and day-flying moths and insects, and this law may also require that flowers which only open at night should, like insects which only fly at night, be white or comparatively very subdued in colour. J. S. G.

Elements of Descriptive Geometry. By J. B. Millar, B.E. (Macmillan, 1878.)

THANKS to Messrs. Kempe, Hart, and other writers on Linkages, we are able "Curvo dignoscere rectum," and "Parallels design Sure as Demoivre" could. The title of the work before us shows that it is not concerned with such elementary details as those which most naturally find a place in works on practical geometry. Chasles in describing the aim of Monge's great discovery, says:—"La géométrie descriptive, en effet, qui n'est que la traduction graphique de la géométrie générale et rationnelle, servit de flambeau dans les recherches et dans l'appréciation des résultats de la géométrie analytique; et par la nature de ses opérations, qui ont pour but d'établir une correspondance complète et sûre entre des figures effectivement tracées sur un plan et des corps fictifs dans l'espace, elle familiarisa avec les formes de ces corps, les fit concevoir idéalement, avec exactitude et promptitude, et doubla de la sorte nos moyens d'investigation dans la science de l'étendue." Mr. Millar's book is a very serviceable exposition of the subject as thus described, and he has prefixed a short introduction on solid geometry. A good English text-book on this branch (solid geometry) is yet a desideratum. The plan on which the figures are arranged and drawn is, we think, likely to aid the student in his working out the propositions in the text.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Hughes's Microphone

MR. EDISON finds a resemblance between his carbon telephone and my microphone.

I can find none whatever; the microphone in its numerous forms that I have already made, and varied by many others since, is simply the embodiment of a discovery I have made, in which I consider the microphone as the first step to new and perhaps more wonderful applications.

I have proved that all bodies, solid, liquid, and gaseous, are in a state of molecular agitation when under the influence of sonorous vibrations, no matter if it is a piece of board, walls of a house, street, fields, or wood, sea or air, all are in this constant state of vibration, which simply becomes more evident as the sonorous vibrations are more powerful. This I have proved by the discovery that when two or more electrical conducting bodies are placed in contact under very slight constant pressure, resting on any body whatever, they will of themselves transform a constant electrical current into an undulatory current, representing in its exact form the vibrations of the matter on which it reposes; it requires no complicated arrangement and no special material, and to most experimenters the three simple iron nails that I have described form the best and most sensitive microphone. But these contact points would soon oxidise, so naturally I prefer some conducting material which will not oxidise.

Mr. Edison's carbon telephone represents the principle of the varying pressure of a diaphragm or its equivalent on a button of carbon varying the amount of electricity in accordance with this change of pressure; it represents no field of discovery, and its uses are restricted to telephony.

The three nails I have spoken of will not only do all, and that far better than Edison's carbon telephone in telephony, but have the power of taking up sounds inaudible to human ears, and rendering them audible, in fact a true microphone; besides it has the merit of demonstrating the molecular action, which is constantly occurring in all matter under the influence of sonorous vibrations.

Here we have certainly no resemblance in form, materials, or principles to Mr. Edison's telephone. The carbon telephone represents a special material in a special way to a special purpose.

The microphone demonstrates and represents the whole field of nature, the whole world of matter is suitable to act upon,

and the whole of the electrical conducting materials are suitable to its demonstrations.

The one represents a patentable improvement, the other a discovery too great and of too wide bearing for any one to be justified in holding it by patent, and claiming as his own, that which belongs to the world's domain. D. E. HUGHES

London, July 2

Insects Corroborative of the Nativity of Certain Plants

WHETHER certain plants are, or are not, natives of Britain is a question that often exercises botanists, and any new evidence on the subject is always acceptable. It has recently occurred to me that a certain kind of evidence may be obtained by studying the insects attached to such plants. The question is one of interest not only to phyto- but also to zoo-geographers; for if the species of plant to which an insect is restricted is proved not to be indigenous then the insect cannot be indigenous either. If, on the other hand, the plant is only doubtfully an alien, and the insect is not one that might be easily introduced, then the probability is that the plant is a true native.

The plant that has suggested this idea to me is the wild or yellow balsam, *Impatiens noli-me-tangere*. This plant is reported from twenty-seven counties or vice-counties, but in most of these it seems to be admittedly an "introduction." Mr. H. C. Watson, the indefatigable author of the "Cybele Britannica," &c., seems to think that its claim to being indigenous is very slight, for he writes ("Topographical Botany," part 2, p. 607):—"If the *Noli-me-tangere* be really native here it must be so very locally: say, in North Wales and Westmoreland." Sir J. D. Hooker ("Student's Flora," first edition, p. 80) says, "Probably wild in North Wales, Lancashire, and Westmoreland;" Prof. Babington ("Manual," seventh edition, p. 72) does not mark it is an introduction, but Hooker and Arnott ("British Flora") regarded it with doubt; finally Hudson ("Flora Anglica," 1762, p. 332) thought it in his day truly wild in Westmoreland. It is evident, therefore, that the *Impatiens noli-me-tangere* is looked upon with suspicion by many of the present race of botanists, and probably rightly so in many of the "stations."

There are two species of Lepidoptera attached to this plant, and, I believe, restricted to it. One of these—*Lygris reticulata*—has been for a number of years known as a native of Westmoreland, where, on the banks of Windermere, it occurs very rarely. Its connection with the *Impatiens* in this country was not, however, known till very recently, when Mr. J. B. Hodgkinson, a well-known Yorkshire naturalist, traced it to its headquarters amongst the plant, where he also, still more recently, found the other Lepidopteron—*Penthina postremana*—which is attached to the balsam. Both of these insects are far from common (though *Lygris reticulata* is, like its food-plant, widely distributed—even as far as Siberia), and their occurrence in Westmoreland seems to me conclusive that the *Impatiens* is really indigenous there.

As apparently opposed to my theory, it must not be forgotten that there are several plants, certainly introduced into Britain, which have insects attached and restricted to them. Amongst others are the spruce-fir and the larch. On the spruce the following insects occur: *Eupithecia togata*, *Semasia nanana*, *Asthenia strobilella*, *Coccyx hercyniana*, &c., and on the larch *Eupithecia lariciata*, *Boarmia crepuscularia*, *Spilonota laricana*, *Coleophora laricella*, &c. But it must be remembered that the spruce and larch are perennial trees (while the *Impatiens* is an annual plant), and that they are frequently imported in the form of young trees, or as undressed timber, and sent hither and thither all over the country. Hence the insects attached to them have many chances of being introduced, and of establishing themselves where the conditions are favourable.

It is possible that some of the insects I have last mentioned may have transferred themselves from the native coniferæ to the introduced ones, but I do not think this is likely. A few species live on the introduced as well as the native trees, as, for example, *Myelois abietella*, upon scots-fir and spruce, and the rare beetle *Dendrophagus crenatus*, upon scots-fir and larch, as I noticed when investigating the natural history of Aberdeenshire some years ago.

It is desirable that all the "stations" in which there is any doubt about the introduction of the *Impatiens* should be searched for the insects mentioned above, for it is not likely that they are confined to Westmoreland; and should they be found in any other locality, the probability is, it seems to me, that there the plant is really indigenous. F. BUCHANAN WHITE

Perth, July 5

Physical Science for Artists

SOME years ago, in Madeira, we had been watching a glorious sunset from the hills above Funchal; and, on turning to go eastward, we saw the sky before us suffused with a bright rosy tint, which ended abruptly beyond the Desertas, at some little distance above the horizon-line of the Atlantic.

At first it did not occur to us what was the cold blue-grey form that rose into the pink flush above, slowly losing its definition of outline as it gradually grew higher.

But this strange silhouette had so distinctly mountain outlines that, almost at once, we recognised the fact that we were looking at the shadow of Madeira cast by the setting sun on the mist.

This phenomenon may not be unusual, but I do not recollect having seen it described; and it is perhaps sufficiently different from the phenomena described by Prof. Brücke and Mr. F. Pollock to be worth recording. G. HUBBARD

Remarkable Form of Lightning

I AM able to confirm the fact that lightning occasionally takes the "punctuated" form described by Mr. Joule in NATURE, vol. xviii. p. 260. Some forty years ago, in a thunderstorm which I had the good fortune to witness at Ampton, in Suffolk, the lightning (with heavy rain) was almost incessant for half an hour or more, and about a quarter of the flashes (speaking from memory only) presented this unusual appearance. I have often looked out for it since, but only once with success, and then it only showed itself in a single flash out of many. On both occasions the "punctuated" flashes presented in general a curved or sinuous line without sharp angles; and two or three of them in the first-mentioned storm *appeared* to my eye as closed curves, one an almost perfect figure of 8; but their dazzling brightness made it impossible to speak to this with certainty.

London, July 8 E. J. LAWRENCE

Microscopy. The Immersion Paraboloid

THE immersion paraboloid illuminator exhibited at the recent *soirée* of the Royal Society as designed by me, proves to have been anticipated in principle and construction by Dr. John Barker, of Dublin, from whom a paper on the subject will be found in the *Proceedings* of the Royal Irish Academy for 1870.

An immersion paraboloid illuminator was also described by Mr. Wenham in the *Transactions* of the Royal Microscopical Society for 1856. My paper on the subject appeared in the *Monthly Microscopical Journal* for August, 1877, but that journal being defunct, I ask you to allow me to credit these gentlemen with a priority which, on perusing their papers, I find to be due to them. I ought to add that, until the construction by Messrs. Powell and Lealand of my illuminator, the device had never come into practical use, and that, so far as I can learn, no reference to it exists in any optician's catalogue or text-book on the microscope. JAMES EDMUNDS

Review of Henfrey's Botany

ALLOW me to correct an error which Mr. Bennett has made in his review of "Henfrey's Elementary Course of Botany" (NATURE, vol. xviii. p. 217). He adds a note as follows:—

"Evidently by an error of the press, the continued fraction of which the most common angles of divergence are successive convergents, is given as $\frac{1}{2}+\frac{1}{1}+\frac{1}{1}$, instead of $\frac{1}{2+\frac{1}{1+1}}$, &c., a correction needful to render the sentence intelligible to the student."

My note (p. 44) is as follows:—

"The mathematician will observe that these fractions are the successive convergents of the continued fraction $\frac{1}{2}+\frac{1}{1}+\frac{1}{1}$, &c."

I subjoined it for the sake of *mathematical* students only, who would know what Mr. Bennett does not seem to be aware of, that the method of writing the continued fraction I have adopted,

is simply a convenient way of expressing it in one line; and it is *not* printed as he has misquoted it above.

GEORGE HENSLOW

6, Tichfield Terrace, Regent's Park, N.W.

[I am obliged to my friend Mr. Henslow for correcting my oversight in not accurately noting the form of his formula. The fact, however, that the sentence is, as, Mr. Henslow admits, put in a form which is adapted for "mathematical students only," in a work intended for beginners, seems to furnish a strong justification of the main point of my criticism.—A. W. B.]

Alumina

IT may interest your readers to know that pure alumina dissolved nearly to saturation before the blowpipe in an *acid* flux, such as a bead of phosphoric acid, invariably causes that to assume a pale but beautiful sky blue on cooling.

In an *alkaline* flux such as a bead of boric acid containing sufficient soda to dissolve it to saturation, alumina causes the bead to assume a pale red colour on cooling.

The greatest care has been taken to ascertain that the materials are absolutely free from any metallic or other oxide which might produce such colours, and the resulting beads have been shown to several gentlemen, as Messrs. Hunt and Roskell, Mr. Hutchings of Freiberg, and others.

Might not these facts then afford us some clue (so much wanted) to the cause of coloration in the sapphire and ruby?

London, July 1 W. A. ROSS

A Subject-Index to Scientific Periodical Literature

I HAVE been occupied for years in drawing up a classified index, not only to the titles of papers, but to what is still more wanted, to the facts contained in those papers. As yet I have met with scant encouragement. A. RAMSAY

Kilmorey Lodge, 6, Kent Gardens, Ealing, W., July 8

CLUB-ROOT

ALL our readers who are agriculturists or practical gardeners will be familiar with the disease called in England "Club-root," or "Finger and Toes," or "Clubbing." It seems almost to confine its ravages to cruciferous plants, and often causes great destruction to large crops of turnips, cabbages, cauliflowers, not to mention what disappointments it may occasion to the growers of wallflowers, Brompton stocks, candytufts, and many other favourite flowers belonging to this large natural family. Not only is it well known, but it has often been written about, as the pages of our contemporary, the *Gardeners' Chronicle*, and most works on the cultivation of gardens, will abundantly prove.

The question of what did it consist of was often asked, and the answer was that it was caused by some insect or another, and some poor beetles and flies were signalled out as those which laid their eggs in the tissues of the young roots of the plants attacked, and, if we are not mistaken, this is the general belief to this present moment. The explanation never was, however, satisfactory. True, in the advanced stage of this disease insect larvæ were to be found in the club-like swellings of the roots; but in the very early stages no trace of larva or egg of any insect was to be seen, and yet the club-root disease was clearly there.

In the *Botanische Zeitung* for May 14, 1875, there appeared a short abstract of a paper read by M. Woronin, before the Botanical Section of the Natural History Society of St. Petersburg, on the 5th of March of the previous year, on the cause of this disease, and within the last few weeks we have received the full memoir, illustrated with upwards of fifty figures. This memoir is in Russian, but, thanks to a colleague (Prof. R. Atkinson), the writer has been able to glean a notion of its most interesting contents, in which he has been much assisted by the beautiful figures. The disease is known in Russia as "Kapustnaja Kila" (Kapusta = Cabbage, Kila = Hernia). About three years since it was so extremely prevalent that the vegetable crops about St. Petersburg failed, and the government ordered an investigation, from which much information was obtained as to the means adopted in different countries for its cure: such as sowing the ground, before planting the crop, with common salt, wood ashes, or, before all, soot. Every one knows, too, that in transplanting the young crucifers into their permanent beds that it is customary to pinch off the swollen portions, and then, if favourable weather followed, the newly-formed roots could well keep ahead of any fresh appearance of the disease. But M. Woronin went scientifically to work, and he was not long in discovering that the cause of the disease was a parasitic vegetable which seemed to have some affinities with the Myxomycetes on the one hand, and the Chytridiaceæ on the other, and the result of constant researches carried on through 1875, 1876, and last year, have resulted in nearly the whole life-history of this new plant being discovered. It is called *Plasmidiophora brassicæ*, and is decidedly very nearly allied to the Chytridia, but the new forms of this group daily coming to light, appear so different in their development, that much more must be known about them ere any satisfactory classification can be attempted. One most striking feature in the new plant is indicated by its generic name; this will be best understood by a short history of the plant's life. Take an old well-developed knob off a club-root, and examine the tissue; most of the parenchymatous cells will be found enlarged, their starchy contents gone, and they themselves gorged with a mass of spore-like bodies; by the ordinary disintegration of the cellular tissue these spores will get released, and after a lapse of six days, out of each spore will proceed the whole of the contents, which, colourless, but nucleated, will move about like so many minute amœba; these plasmodia will then attach themselves to the delicate root-hairs of the nearest young cruciferous seedling. One end of the plasmodium is attenuated like a cilium. The spores soon penetrate into the cells, where they will look just like Myxamœbæ. Filling the cells up with delicate plasmodic projections, they will next soon develop lots of spores, which will further contaminate the cellular tissue of the root, and in process of time the formation of the clubbing will be seen.

Sometimes the ripe spores are spherical, sometimes they are twin-like, or lenticular. If cabbage or turnip seeds be sown in a watch-glass and supplied with distilled water, and shortly after the first appearance of germination, a number of spores of *Plasmidiophora brassicæ* be added to the water, these will be found to at first float freely in the water, but sooner or later will sink and attach themselves to the delicate root-hairs of the little seedlings, and in this way their whole history, so far as now known, may with facility be traced. It seems noteworthy that the whole mass breaks into spores all at once, as in Chytridium proper. There would seem to be as yet no conjugation detected, and the plasmodia would appear as if they absolutely engulfed the starch granules on which they feed.

It must be a matter of regret that this memoir is written in a language known unfortunately to so few scientific botanists. If the learned author knew only Russian it would be absurd and unreasonable to record this regret, but to one knowing French and German, as M. Woronin does, it would have been no trouble to have increased a hundredfold the grateful readers of this important memoir.

E. PERCEVAL WRIGHT

SCIENCE IN SCHOOLS

THE following article on Sir John Lubbock's Bill on the introduction of science in elementary schools appears in Monday's *Times*:—

The rejection of Sir John Lubbock's motion for the addition of elementary science, or, rather, as the matter was more happily put by Dr. Lyon Playfair in the course of the debate, of elementary knowledge of common things, to the subjects for which grants are given under the education code, although an inevitable and foregone conclusion, is not on that account the less to be deplored. As happens in many similar cases, the argument was all on the side of the minority, and Lord G. Hamilton, in opposing the suggestion on the part of the Privy Council, was only able to say that its adoption would, perhaps, entail some temporary uncertainty about the subjects in which inspectors would be required to examine and children to pass. If schools existed for the convenience of inspectors, or even in order that children might not be troubled by uncertainties, the objection would have been a valid one; but upon any other supposition it seems to tell against, rather than in favour of, the contention which it was intended to support. The nation is spending large and rapidly increasing sums of money upon schools, and it will every year become a matter of greater urgency that these sums should not be misapplied, either by the omission from the code of subjects which would be useful or by the inclusion of others which have no apparent tendency to promote the attainment of the ends to which education is supposed to be directed. These ends, in the case of a peasant child, are presumably to render him a more useful and a better conducted member of society than he would become by the unaided light of nature; and it is obvious that the means to their attainment are twofold—first, to cultivate the intelligence in such a way as to facilitate the acquirement and the application of knowledge; and, secondly, to impart the knowledge which has to be applied. Until a comparatively recent time, however, the imparting of knowledge was considered to be the sole purpose of education and to be in itself the best means of mental training; so that educationists occupied themselves more about the seed than about the soil, and were chiefly concerned to teach those things which they thought it most important that a child should know. The instruction given to the poor for many years was almost limited to reading, writing, arithmetic, and elementary religious instruction, while that imparted to the rich was laid upon the same foundation, and was only carried further because the pupils had more time at their disposal. In the employment of this time the instructors could only teach what they knew; the most famous public schools and the two great Universities restricted themselves to giving their pupils some knowledge of classics and mathematics.

As soon as physiologists had discovered that all the faculties of the intellect, however originating or upon whatever exercised, were functions of a material organism or brain, absolutely dependent upon its integrity for their manifestation, and upon its growth and development for their improvement, it became apparent that the true office of the teacher of the future would be to seek to learn the conditions by which the growth and the operations of the brain were controlled, in order that he might be able to modify these conditions in a favourable manner. The abstraction of the "mind" was so far set aside as to make it certain that this mind could only act through a nervous structure, and that the structure was subject to various influences for good or evil. It became known that a brain cannot arrive at healthy maturity excepting by the assistance of a sufficient supply of healthy blood—that is to say, of good food and pure air. It also became known that the power of a brain will ultimately depend very much upon the way in which it is habitually exercised, and that the practice of schools in this respect left a great deal to be desired. A large amount of costly and pretentious teaching fails dismally for no other reason than because it is not directed by any knowledge of the mode of action of the organ to which the teacher endeavours to appeal; and mental growth in many instances occurs in spite of teaching rather than on account of it. Education, which might once have been defined as an endeavour to expand the intellect by the introduction of mechanically compressed facts, should now be defined as an endeavour favourably to influence a vital process; and, when so regarded, its direction should manifestly fall somewhat into the hands of those by whom the nature of vital processes has been most completely studied. In other words, it becomes neither more nor less than a branch of applied physiology; and physiologists tell us with regard to it that the common processes of teaching are open to the grave objection that they constantly appeal to the lower centres of nervous function, which govern the memory of and the reaction upon sensations, rather than to those higher ones which are the organs of ratiocination and of volition. Hence a great deal which passes for education is really a degradation of the human brain to efforts below its natural capacities. This applies especially to book work, in which the memory of sounds in given sequences is often the sole demand of the teacher, and in which the pupil, instead of knowing the meaning of the sounds, often does not know what "meaning" means. As soon as the sequence of the sounds is forgotten nothing remains, and we are then confronted by a question which was once proposed in an inspectorial report:—"To what purpose in after-life is a boy taught if the intervention of a school vacation is to be a sufficient excuse for entirely forgetting his instruction?"

In order to avoid such faulty teaching, few agencies are more valuable than what are technically called "object" lessons, in which the faculties of the pupils are exercised about things instead of about words; and the suggestion of Sir John Lubbock would lead to object lessons of a very useful character. To be taught something about gravitation, about atmospheric pressure, about the effects of temperature, and other simple matters of like kind, which would admit of experimental illustration, and which would call upon the learner to make statements in his own words instead of in those of somebody else, would be so many steps towards real mental development. At the end of a vacation, even if the facts of any particular occurrence had become somewhat mixed, the pupils would nevertheless preserve an increased capacity for acquiring new facts, and would probably retain these for a longer period; and such are precisely the changes which it should be the province of education to bring about. We would even go further than Sir John Lubbock, and in elementary schools would give an important place to the art of drawing, which teaches accurate observation of the forms of things. The efforts of a wise teacher should always be guided with reference to the position and surroundings of a child at home, and should seek to supplement the deficiencies of home training and example. Among the wealthier classes the floating information of the family circle often, though by no means always, both excites and gratifies a curiosity about natural phenomena; but among the poor this stimulus to mental growth is almost, if not entirely, wanting. An explanation of the physical causes of common events, such, for instance, as the rising of water in a pump, would usually be a revelation to the pupils of a Board School, and would start them upon a track which could hardly fail to render them more skilful workers in any department of industry, and which might even lead some of them to fortune. A wise and benevolent squire set on foot many years ago a school for the children of his labourers, in which drawing and the elements of natural science were carefully taught; and the result was that the children educated there, instead of remaining at the plough's tail, passed, in an astonishingly large number of cases, into positions of

responsibility and profit. On every ground, therefore, we hope that Sir John Lubbock's proposal will at no distant time be adopted by Parliament; but in the meanwhile there is a still more important department of teaching which is wholly neglected, and concerning which the deficiencies of home instruction are at least equally manifest. We refer to a proper knowledge of the influence of conduct upon life. It should be the duty of every schoolmaster to try and make his pupils understand how production—that is to say, industry—leads to wealth, and how destruction—that is to say, idleness—leads to poverty. The reason why confidence in others is necessary to all enterprise, and the reason why honesty, in the largest sense of the word, is the only root of confidence, should in like manner be enforced by precept and illustrated by example; and such teaching, if it could only be made general, would do more to heal the breach between capital and labour than all the panaceas of all the politicians who have ever sought to figure as the "friends of the working man."

OUR ASTRONOMICAL COLUMN

TEMPEL'S COMET, 1873, II.—Up to the time of writing it would appear that this comet has escaped detection. Even if there be no great error in the calculated position, its faintness must render discovery difficult in the summer skies, but it may be hoped nevertheless that a vigorous effort will be made in the next period of absence of moonlight to recover the comet, as in the event of want of success in the present year, it will be probably lost, or in the same case as the short-period comet of De Vico of 1844, which, being missed at the second return in 1855, has not been again observed. M. Schulhof has communicated to the French Academy a further ephemeris of Tempel's comet, from which are extracted the places subjoined:—

At Paris midnight.	R.A. h. m.	N.P.D. ° ′	At Paris midnight.	R.A. h. m.	N.P.D. ° ′
July 13	15 31·6	93 18	July 29	15 47·6	100 8
,, 17	15 34·4	94 55	Aug. 2	15 53·8	101 57
,, 21	15 38·0	96 36	,, 6	16 0·8	103 46
,, 25	15 42·4	98 21	,, 10	16 8·6	105 36

During this interval the comet's theoretical intensity of light will be only three times that it possessed at the date of the last observation in 1873, when it was the faintest object that could be observed in a dark field with a 7-inch refractor. A few days' difference in the date of perihelion passage, which is probable enough, changes the geocentric path materially, so that the search must be extended to some distance on each side of the calculated place for the day of observation.

In its present orbit the comet cannot approach the planet Jupiter within 0·62, and with M. Schulhof's period of revolution it is easy to see that there will be no near approximation of the two bodies during the next twenty years—in such case the perihelion passages must always occur at a season of the year when observations of the comet would be barely, if at all, practicable. Hence an additional reason for a very close search in the present summer.

THE "TEMPORARY STARS" OF KEPLER AND ANTHELM.—The objects observed by Kepler in 1604 and by Anthelm in 1670, which Sir John Herschel was wont to describe as "temporary stars," but which there is, nevertheless, reason to believe to be still visible as telescopic stars, will not escape the attention of observers who are interested in the variables, at this season. As mentioned some time since in this column, Prof. Winnecke remarked, in 1875, a star of the twelfth magnitude on his scale, which is very near the calculated place of Kepler's famous star, and to the place of a star entered upon Chacornac's Chart, No. 52, as a *tenth* magnitude. We are able to state that no star was discernible in this position with 7-inches aperture on several occasions in 1872-74. The position of Winnecke's star for 1855·0 is in R.A. 17h. 21m. 49·3s., N.P.D. 111° 19′·3; it therefore precedes No. 16,872 of Oeltzen's Argelander by 33s. and is north of it 2′: Argelander's star is of 8·9m. and the best reference point in examination of the neighbourhood. For 1870·0 we have:—

	R.A. h. m. s.	N.P.D. ° ′	
Kepler's star 1604	17 22 51	111 22·0	Schönfeld's reduction from observations of Fabricius.
Chacornac's star 10m.	17 22 43	111 22·5	Read off from his chart, therefore only approximate.
Winnecke's star 12m.	17 22 43	111 20·8	Observed at Strasburg.
Argelander's star 8·9m.	17 23 16	111 22·8	

There is also a star of about 12m. in R.A. 17h. 22m. 57s., N.P.D. 111° 24′·4, and therefore as near to the calculated position of Kepler's star as Winnecke's object, which has not shown any variation during several years. The difference of magnitude noted by Chacornac and Winnecke rather points to their star as the one to be closely watched.

The place of the star discovered by Anthelm in 1670 has been calculated from the observations of Picard and Hevelius by Prof. Schönfeld, and from those of Picard only (as given in the *Histoire Céleste* of Lemonnier) by Mr. Hind, their results differing only 2s. in R.A., and 0′·4 in N.P.D. The telescopic star 11·12m., which is now visible almost in the same position, was meridionally observed at Greenwich in 1872, the result for 1880·0 being R.A. 19h. 42m. 45·1s., N.P.D. 62° 58′ 32″. Variation extending to more than one magnitude has been remarked in this object, during the last twenty-five years, thus, with the near coincidence of position affording strong indication that it may eventually prove to be the star which suddenly brightened up in 1670. A star of similar magnitude follows it 12·5s., about 3′ to the north, and another follows at 22·5s., about 2′ northerly. In the years 1872-74 the presumed star of Anthelm was judged to be at times sensibly equal to the first of these stars following it, at others decidedly fainter—even at the first glance.

JEREMIAH SHAKERLEY.—The transit of Mercury on November 2, 1651, it will be remembered, was predicted by Jeremiah Shakerley, a young devotee of astronomy, who, finding by the tables in his hands, apparently founded upon the observations of Horrox, that it would not be visible here, undertook the, at that period, great voyage to India for the purpose of witnessing the phenomenon, which he observed at Surat. Vincent Wing mentions this circumstance in his *Astronomia Britannica*, where the following passage occurs:—"Hanc conjunctionem prædixit idem D. Shakerlœus in *Colloquio* seu *Disceptatione*, *De Mercurio in Sole Videndo*, et postea ipse transmigrans in *Indiam*, conjunctionem hanc insignem ibi videbat, eamque amicis in *Anglia* communicavit, ut patet ex Literis ad *Christophorum Townlœum*, *Henricum Osbornum*, *Londinensem*, aliosque missis."

No work of Shakerley's exists in the libraries of the British Museum, the Royal Observatory, or the Royal Astronomical Society. His *Tabulæ Britannicæ* are in the possession of the Royal Society, and we believe are also found in the Cambridge University Library. The immediate object of this note is to inquire if any reader of NATURE has met with the other works of Shakerley mentioned by Lalande in his *Bibliographie*, or with a publication in which the transit of Mercury in 1651 was predicted.

THE GENESIS OF LIMBS

WHY are our limbs so much alike and yet so different? What do our limbs stand for as compared with the bodies of other animals? Whence have limbs such as ours arisen? What *is* a limb?

The word *limb* is the Anglo-Saxon word *lim*, most probably connected with the Latin *limbus*—the border, outer edge, or extremity of anything, and thence applied to any attached, projecting, or out-lying portion.

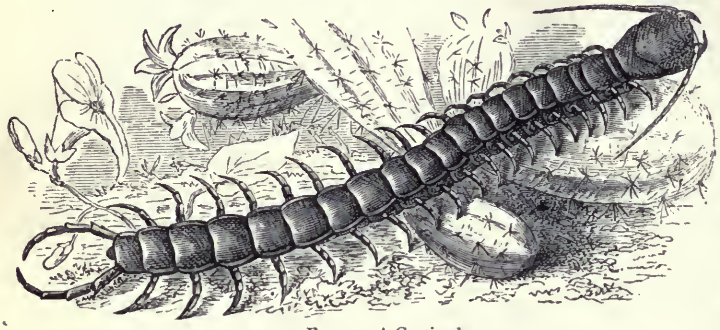

FIG. 1.—A Centipede.

But there are projecting portions of animal bodies essentially like our own body which are not called limbs, *e.g.*, the dorsal and anal fins of fishes, while yet that name is freely bestowed upon structures which have no relation to our limbs save a relation of analogy from similarity of use, as, *e.g.*, the legs of insects or the arms of star-fishes. Insects and their allies present certain resemblances and differences carried to a higher degree than in us, and which may be here adverted to. The difference in shape between the limbs of the right and left sides in us is minute and accidental. Our *bilateral* symmetry is complete, but in many crustaceans the shapes of the right and left great claws differ to a large extent. The resemblance between the thoracic and pelvic limbs in us is great, but the resemblance between the successive legs of many arthropods is much greater, especially in the class of centipedes, where the successive segments of the body, with their appendages, exhibit *serial* symmetry carried to the highest degree. The amount of likeness, as regards *serial symmetry*, which exists between our pairs of limbs is less than exists in many back-boned creatures, while at the same time there are a great many others in which it is not carried nearly so far as it is in ourselves. These varying degrees of serial symmetry are such that upon the theory of evolution we must suppose that if this serial symmetry originally existed, it must have been lost and reacquired perhaps several times to produce what we see before us in the existing creation.

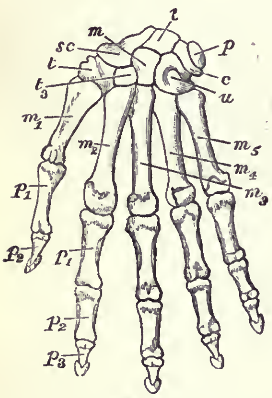

FIG. 2.

FIG. 3.

FIG. 2.—Anterior (palmar) surface of the skeleton of man's hand —*c*, cuneiforme: *l*, lunare; *m*, magnum; m¹, metacarpal of thumb; m^2–m^5, metacarpals of the four fingers; *p*, pisiforme; P^1, first phalanx of the thumb and four fingers—*i.e.* of the five "digits;" P^2, second phalanx of the five digits; *P*3, third, or ungual phalanx; *sc*, scaphoides; *t*, trapezium; *tz*, trapezoides; *u*, unciforme.

FIG. 3.—Dorsum, or upper surface, of skeleton of right foot.—*a*, astragalus; c^1, ento-cuneiforme; c^2, meso-cuneiforme; c^3, ecto-cuneiforme; *ca*, calcaneum; *co*, cuboides; *h*, distal phalanx of hallux; m^1, metatarsal of hallux; m^2–m^5, metatarsals of the four outer toes; *n*, naviculare.

Thus if we compare with the structure of the human hand and foot the same parts in apes, we find that in them the toes (or digits of the foot), instead of being short like ours, are long and mobile like our fingers, while the great toe (or hallux) is set out at an angle from the others, to which it is powerfully opposable. At the same time the main points of structure of the ape's foot remain like our own, and thus while it is morphologically a foot, it is functionally more or less of a hand. Here, therefore, serial symmetry is already more complete than in us.

If we descend to hoofed beasts, *e.g.*, the hog, the giraffe, or the horse, we find the number of digits equally and simultaneously reduced in both the fore and the hind limb, and while in the two former creatures the third and fourth digits of each extremity are increased in size at the expense of the others, in the horse there is but one digit so increased—the animal walking upon but four digits, which answer respectively to our two middle fingers and our two middle toes.

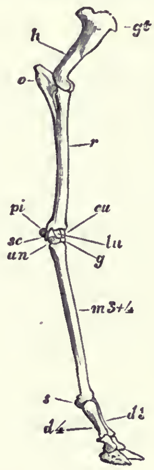

FIG. 4.

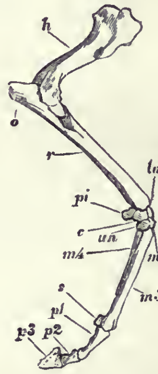

FIG. 5.

FIG. 4.—Right pectoral limb of a Giraffe.—*cu*, scaphoides; *d*3, proximal phalanx of third digit; d^4, proximal phalanx of fourth digit; *g*, magnum; *gt*, great tuberosity of the humerus; *h*, shaft of the humerus; *lu*, lunare; m^{3+4}, united metatarsals of third and fourth digits; *o*, olecranon; *pi*, pisiforme; *r*, radius; *sc*, cuneiforme; *un*, unciforme.

FIG. 5.—Right pectoral limb of Horse.—*c*, cuneiforme; *h*, humerus; *lu*, lunare; m^3, metacarpal of the third digit—the only one fully developed; m^4, rudimentary fourth metacarpal; *mg*, magnum; *pi*, pisiforme; p^1, proximal phalanx; p^2, middle phalanx; *p*3, third or ungual phalanx; *s*, sesamoid; *un*, unciforme.

It is, then, quite a mistake to regard the ox's hoof as answering, morphologically, to the horse's hoof "cloven;" each single hoof of the horse answers only to the inner division of each double hoof of the ox or giraffe. Now in all these creatures we find a still further increase in serial symmetry as compared with the apes and man.

If, however, we turn to such an animal as the mole we find a much decreased degree of such symmetry, the fore-limb being of enormous strength, with its bones shortened and broadened out, while the hind-limb is slender and deli-

FIG. 6.

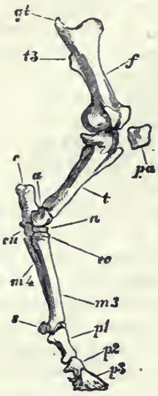

FIG. 7.

FIG. 6.—Right pelvic limb of Giraffe.—*a*, astragalus; *c*, calcaneum; *cu*, cuboides; *d*3, proximal phalanx of third digit; *d*4, proximal phalanx of fourth digit; *f*, femur; *f'*, rudiments of fibula (the line is not continued far enough—the rudimentary fibula is a small ossicle reposing on the upper surface of the calcaneum, as shown in the figure); m^{3+4}, metatarsals of digits 3 and 4 united into one "cannon-bone"; *pa*, patella; *t*, tibia.

FIG. 7.—Skeleton of right pelvic limb of Horse.—*a*, astragalus; *c*, calcaneum; *cu*, cuboides; *ec*, ecto-cuneiforme; *f*, femur; *gt*, great trochanter; *m*3, metatarsal of third digit; m^4, rudimentary fourth metatarsal; *n*, naviculare; *pa*, patella; p^1, p^2, and p^3, first, second, and third phalanges of the third and only digit; *s*, sesamoid; *t*, tibia; *t*3, third trochanter.

cate. The mole works underground with such exceeding rapidity that it has been said to fly beneath the soil, but in the beast which really does fly—the bat—serial sym-

FIG. 8.—Hand of Bat (*Pteropus*).—m^1–m^4, metacarpals of the four fingers; *p*, pollex, with a very short metacarpal; *sc*, scaphoides.

metry is still less developed. The framework of the bat's wing consists of the very same bones which exist in the human arm and hand, only exceedingly elongated and slender. The four fingers—wonderfully drawn out—are connected together (and to the body and legs) by a delicate web of skin. The foot is a striking contrast to the enormously enlarged hand, being small in size with short toes. And yet, though serial symmetry is thus disguised in the bat, it nevertheless shows itself in other ways more or less noteworthy. The outer bone of the fore-arm—the *ulna*, is incompletely developed, and the corresponding bone of the leg—the fibula, is also incompletely developed. But much more than this, in some bats we find outside the

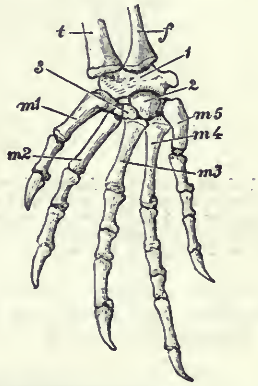

FIG. 9.—Left foot of a Monitor Lizard (*Varanus*).—*f*, fibula; m^1–m^5, the five metatarsals, m^1 being that of the hallux; *t*, tibia; 1, astragalo-calcaneum; 2, cuboides; 3, ecto-cuneiforme.

elbow-joint a distinct and separate little bone which quite answers to the knee-pan (or *patella*) of the leg—a most exceptional case of serial homology.

The creatures just referred to are all mammals, but birds and reptiles present us with some instructive examples both of serial homology and discrepancy. In ourselves and in all beasts, the motion of the foot upon the leg takes place between the long bones of the latter (tibia and fibula) and the tarsus. In the crocodile, or

FIG. 11.—Right foot of Emeu.—*a*, astragalus; d_2–d_4, second, third, and fourth digits; *m*, metatarsals anchylosed together except at their distal ends; *t*, tibia; t_2, distal tarsal element.

monitor, it is not so, but the upper part of the ankle, or tarsus (answering to our astragalus and os calcis), is firmly and immovably fixed to the leg bones, while the lower part of the tarsus is firmly fixed to the metatarsals. Thus in the crocodile, or monitor, motion does not take place between the whole ankle and the leg, but in the middle of the ankle (or tarsus) itself.

In the leg of a bird there at first sight seems to be no

tarsus at all, nor any bones which we can with certainty call "metatarsal." We have only one single long bone, at the lower end of which are three or four articular surfaces for the three or four toes. The study of the very young bird, however, has shown us that though no tarsus can be distinguished in the adult, yet such a part does exist for a certain brief period of the bird's life and then disappears.

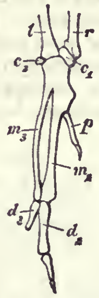

Fig. 10.—Right hand of Ostrich.—c^1, radial carpal ossicle; c^2, ulnar carpal ossicle; d^2, proximal phalanx of the index digit which has three phalanges; $d3$, phalanx of third digit; l, ulna; m^2 and $m3$, metacarpals of second and third digits anchylosed together and with that of the pollex; p, proximal phalanx of pollex; r, radius.

In its fate we have an interesting resemblance to the condition which we have already found existing in the crocodile, and which condition the bird exaggerates. The upper part of the tarsus becomes not merely firmly fixed to, but indistinguishably united with, the leg-bone, or tibia, while the lower part of the tarsus becomes as indistinguishably united with the coalesced metatarsals, and thus it comes about that no tarsus whatever is distinguishable in the adult. The apparent leg-bone (tibia) is leg-bone with part of the tarsus also; the apparent metatarsal bone is made up of metatarsal bones with the other part of the tarsus also. The movement of the foot on the leg takes place in the bird (as in the crocodile), not between the leg and ankle, but in the middle of the ankle itself.

In the skeleton of the bird's fore-limb, or wing, the hand is strangely different in aspect from the foot. There is hardly any carpus (or wrist) visible. The metacarpus is represented by a single complex bone formed of three metacarpals anchylosed together, and there are only three fingers, which are all more or less rudimentary.

Here serial symmetry is more disguised than ever in the bat, the difference between a bird's wing and a bird's leg being so great. And yet even here we meet with a curious example of the tendency to vary similarly which exists in serially homologous parts; for in the bird's carpus there is a similar arrangement, though less thoroughly carried out, to that which exists in the bird's tarsus. The distal part of the carpus coalesces altogether with the metacarpus (as the distal part of the tarsus does with the metacarpus), but the proximal part remains distinct in the form of two separate carpal bones.

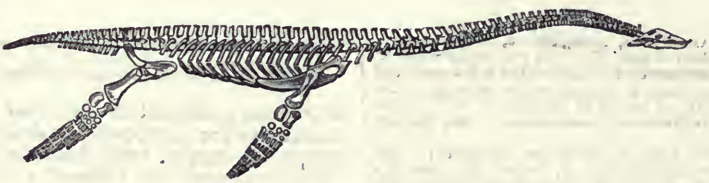

Fig. 13.—Skeleton of a Plesiosaurus.

(*To be continued*)

St. George Mivart

THE OBSERVATORY OF PARIS

ARRANGEMENTS for the future management of the Observatory at Paris are now complete. Contre-Amiral (until recently Captain) Mouchez is appointed director, with M. Maurice Lœwy as sub-director—these appointments taking effect for five years.

M. Mouchez was born at Madrid in 1821, but is the son of French parents. He joined the Naval School at Brest in 1837, and in 1839 commenced his nautical career in the *Fortune*, which was taking part in the blockade of Buenos Ayres. In 1840 he was appointed to the *Favorite*, which proceeded on a circumnavigating expedition extending over five years. Having shown an early aptitude for astronomical observations, he was intrusted with them. On this voyage he became aware of the imperfect determination of the latitudes and longitudes of some of the sea-ports visited, and his attention was directed to the construction of portable instruments for improving them. In 1850 he embarked on board the *Capricieuse*, also destined for a scientific voyage round the world, which, like that of the *Favorite*, occupied five years. He was charged by the Dépôt de la Marine with the survey of the Rio de la Plata and the Brazils, a survey which extended over about 3,000 miles.

In 1860 M. Mouchez was commissioned by the French Government to visit England, for the purpose of reporting upon the system of weather predictions organised by the late Admiral Fitzroy, Leverrier at the time contemplating the establishment in France of his own system of storm-warnings. M. Mouchez, who was enthusiastic in favour of the Fitzroy arrangements, suggested that the *Dépêche anglaise* should be posted in the French ports, and recommended a special meteorological organisation independent of the Observatory at Paris. The proposition, which was carried into effect, is said to have created differences between Leverrier and the Minister of Marine. M. Mouchez greatly interested himself from an early period in his naval career in promoting astronomical and physical studies amongst the officers of the Government marine, and observations while at sea. His views are noticed by Arago in his introductory work for scientific travellers.

In 1867 he commenced the survey of the coast of Algeria, a work which, in consequence of repeated interruptions from his employment on other urgent missions, was not completed until 1877. Thus in 1870, Contre-Amiral Mouchez was sent with the French fleet to the Baltic for the blockade of the Prussian coasts, but the attempted blockade proving a failure, he was recalled and charged with the defence of Havre, which place he succeeded in preserving from a threatened hostile occupation.

In 1874 he was sent to the Island of St. Paul for the observation of the transit of Venus, and next to that of M. Janssen his mission may be considered the most successful. At his suggestion the French Government established, in 1875, an observatory at Montsouris, where naval officers are practised in making astronomical observations, as also intending travellers, on the recommendation of the Société de Geographie. He is a member of the Academy of Sciences in the section of Astronomy,

and of the Bureau des Longitudes, and was for some time a member of the Council of the Observatory. It is understood that M. Bardoux suggested the adoption of the system in operation at the United States Naval Observatory at Washington, and to model the great Paris Observatory after that institution; and as stated above, the appointment of Admiral Mouchez as director, and M. Lœwy as sub-director, are at present intended to be limited to five years, with the same restriction as to future nominations.

M. Maurice Lœwy, who was born at Pesth in 1834, commenced his astronomical career at the Imperial Observatory of Vienna, under the late Prof. Carl von Littrow, on whose recommendation he was transferred to the Observatory of Paris by Leverrier, in 1860. At Vienna he was much occupied with the calculation of the orbits of comets, including the great comet of Donati in 1858, for which body he was one of the first to establish elliptical elements. He succeeded Laugier, as one of the astronomers of the Bureau des Longitudes in 1872, and since 1874 has been charged with the preparation of the *Connaissance des Temps*, the French national ephemeris, and the *Annuaire*, works which have greatly benefited by his energetic superintendence. Under Delaunay's rule, M. Lœwy occupied the position of sub-director of the Observatory of Paris, charging himself with the meridian observations.

The installation of Admiral Mouchez took place on Saturday by the Council of the Observatory, of which M. Dumas is president.

PROF. W. M. GABB

We greatly regret to hear of the death from consumption, on May 30, at his residence in Philadelphia, of Prof. William M. Gabb, who for many years has occupied a very prominent place among American naturalists.

He was born on January 20, 1839, in Philadelphia, and was educated at its High School, being one of the many graduates of whom that institution had reason to be proud. As a boy he was especially interested in mineralogy and palæontology, and at an early age was so fortunate as to secure an engagement with Prof. James Hall, where he had ample opportunity of indulging his tastes. Returning to Philadelphia, he became a member of the Academy of Natural Sciences, and soon commenced the critical study of the fossil invertebrates of the United States, especially those of the cretaceous formation.

In 1860 he entered the service of the Geological Survey of California, under Prof. J. D. Whitney, but returned to the East in 1868, and undertook the geological survey of their lands for the Santo Domingo Land and Mining Company, which, however, was made to cover a considerable portion of the Dominican Republic, and to which he subsequently made several successive visits for the purpose of continuing his work.

During his connection with the Geological Survey of California he made an extended exploration of the peninsula of Lower California, collecting much important geological and biological material.

In 1873 he became connected with the Costa Rican Government, undertaking a general geological and topographical survey of its territory, and combined with it very extensive researches into its natural history and ethnology, sending his collections to the National Museum in Washington. This labour occupied him for about three years. The results of his work have been given to the public in various forms. A full account of the topography, with an elaborate map, appeared in Petermann's *Mittheilungen*, and a paper on the ethnology of the native tribes, published by the American Philosophical Society, is one of standard value.

In the autumn of 1876 he revisited San Domingo, returning to the United States in March last. For many years he has been threatened with pulmonary disease, the extension of which has been checked by his abode in subtropical regions. The unfavourable symptoms, however, increased of late, and he succumbed shortly after his return to Philadelphia.

Dr. Gabb left an extensive manuscript on the geology and palæontology of Costa Rica, which will be published ere long under competent supervision, thus closing a career of energy and activity, not only in the prosecution of researches, but in the elaboration of their results, which has been seldom equalled by a man of his age. It is very rare, indeed, that one man has accomplished so much in so many distinct branches—in geology, geography, palæontology, ethnology, &c.—as the subject of our present notice.

ON THE ANATOMY OF THE ORGAN OF HEARING IN RELATION TO THE DISCOVERY OF THE PRINCIPLE OF THE MICROPHONE OF PROF. D. E. HUGHES, AND THE MAGNOPHONE OF MR. W. L. SCOTT, A.S.T.E.[1]

The two gentlemen whose names appear in the heading of this paper seem to have arrived at the same important result, viz., the extraordinary effect of mobile particles in transmitting sound under certain conditions, by quite independent research. In perusing the interesting accounts of the *microphone* in several scientific journals, but especially an article in the *Electrician* for May 25, in which number also will be found Mr. Scott's statement of the principle, it occurred to me that the transmitting power of the *otoconia* and *otoliths* in the ears of animals bore very pertinently upon this question. We find *otoconia*, or numerous minute particles in all the *Vertebrata*, with perhaps the exception of the bony fishes which have single concretions, or the union of many in one. *Otoconia* are also found in the *Tetrabranchiate Cephalopoda* (*Nautilus*, Fig. 1), the whole of the *Pteropoda*, in the *Pulmonifera inoperculata*, or rather the bisexual *Pulmonifera* (snails and slugs, Fig. 3), there being an operculum in *Amphibola*. On the other hand, in the *Dibranchiate Cephalopoda* (*Sepia*, Fig. 2), all the *Heteropoda* (Fig. 5) and the *unisexual operculate Pulmonifera* (Fig. 4) the ear-sacs contain single *otoliths*.

It will be thus seen that the nature of the auditory concretions is by no means an unimportant element in the classification of animals.[2] Prof. Huxley alludes to the genus *Polyophthalmus*, an Annelidan with eyes in every segment, as a remarkable fact, but this is excelled by his notice of otoliths in the tail of *Mysis flexuosa*,[3] a little pelagic crustacean which I have often had the opportunity of examining.

Every physiologist is aware that there are structural particulars in the ears of *Vertebrata* which show clearly that nature's philosophy is of a more profound character than that to which man has hitherto attained. Indeed if we study the simplest ears in creation, those, for example, of the common *Snail* and of the *Periwinkle*, a most interesting problem is presented to us to solve, namely, the precise function of the numerous otoconia in one case, and of the single otoliths in the other. It is commonly granted that these concretions augment the sonorous undulations by resonance, a view which is borne out by several considerations. If we take two stones and strike them together under water, the head also being immersed, the collision will produce a very loud and peculiar sound, but in order to make the minute otoconia impress one another

[1] By John Denis Macdonald, M.D., F.R.S., Dep. Ins. Gen. R.N., &c.
[2] See a paper by the author in the *Linnean Transactions* for 1860, in which a classification of the Gasteropoda has been attempted.
[3] See *Ann. and Mag. of Nat. Hist.* for May, 1851.

with the rhythmical flow of the undulations of sound, they must be poised off from the walls of the auditory sac. And this is effected, in some instances, by little tubercles on the inner surface as in the *cuttle fish* or as in the *Heteropod*, as shown in Fig. 5 (*h*), the auditory organ of *Cerophora*, in which also large vibratile cilia effect a continual rotatory motion of the spherical otolith. In other cases when otoconia are present, a fine ciliated lining not only prevents the contact of these minute particles with the walls of the sac, but keeps them in constant motion, jostling one another in a remarkable manner. Now when acoustic waves are passing over the auditory organ, it is easy to perceive how their impulses may be imparted to the otoconia, and thereby communicated with augmented effect to the auditory centre.

Whatever may be the intrinsic nature of nervous force it exhibits unmistakable polar properties which would

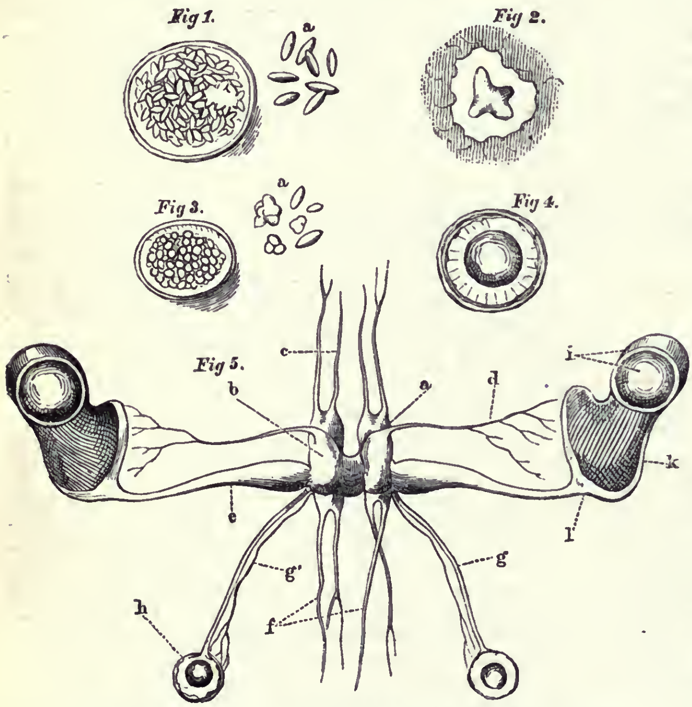

Fig. 1.—Auditory sac of *Nautilus*. *a*, otoconial particles, elliptical.
Fig. 2.—Section of auditory cavity of *Sepia*, with a somewhat cruciform otolith.
Fig. 3.—Auditory sac of *Limax atelis*, &c. *a*, otoconial particles, some of them compound, others of variable size.
Fig. 4.—Auditory sac of *Litorina*, *Geomelania*, or *Cyclostoma*.
Fig. 5.—Cerebroid ganglia and organs of vision and hearing in *Cerophora*. *a*, upper cerebroids; *b*, lower cerebroids; *c*, buccal nerves; *d*, motor nerve of the eye; *e*, optic nerves; *f*, trunks communicating with the pedal ganglia; *g*, pedicle of the auditory sac; *g'*, nerve distributed to the auditory sac; *h*, auditory sac with contained otolith; *i*, meniscus, and lens of the eye; *k*, body of the eye; *l*, retina.

thus place it in the category of the electric force, though no one now would attempt to reason out the identity of the two. It is, however, a new idea that nervous force in the *function of audition* plays an analogous part to the *electric force* in the case of the *microphone*. Moreover, if we look to the anatomy of the ear, we see that provision for a complete circuit is made. Take, for example, the auditory sac (*h*), pedicle (*g*), and nerve (*g'*) of *Cerophora* (Fig. 5). Nothing would appear to be wanting if we admit the nervous centre to be the equivalent of the battery, From all this it would seem to be a rational hypothesis that nervous force in traversing the circuit just indicated under the influence of sonorous undulations is actually transmitted from particle to particle of *otoconia*, or through the revolving *otolith*, as the case may be. But while the *microphone*, or the principle involved in it, affords us some additional light in relation to the physiology of hearing, the study of the anatomy of the ear might give electricians some valuable hints as to the construction of transmitting apparatus. One of Prof. Hughes' transmitters so exactly resembles the natural arrangement of the parts in the middle ear of the higher animals, that some few remarks on this subject may not be out of place here. Many years ago (1847-48) I noticed that a small piece of steel casually lying in the box of a square pianoforte reproduced, with great fidelity, any note, or number of notes, touched on the instrument, by the impact of its own weight meeting the vibrations of the sound-board beneath. Here was, in effect, the basis of the *telephone*, and I would indeed have anticipated the wisdom of the age had I known how to call in the aid of electricity in the simple way that this has been done by Prof. Bell. The fact, however, was made the subject of a paper published in the *Medical Gazette*, in which the *Membrana tympani* and the *Malleus* were compared with the sound-board and steel rod in the case referred to. Moreover, the inference was drawn that while the membrane communicates its vibrations to the ossicles, or small bones, it also causes the *malleus* to percuss the face of the *incus* responsively to the rapid and varied impressions made upon it, a view which borrows additional weight from the fact that in the frog articulation is still persistent where, from the absence of muscles for adjustment it might be considered to be quite unnecessary.

It should also be remembered the handle of the *malleus* extends like a radius from the centre to the circumference of the drum membrane, so as thus to include, without impeding, its three vibrating segments. The centre gives the *key-note* the circumference the *fifth*, and the intervening region the *third*. Only add to this the aural lens or lenticles, the *otoliths*, or the *otoconia*, with the light which the *microphone* has cast upon their function, and we are enabled to form a better conception of the physiology of hearing than has hitherto been possible. The accentuations, piano, forte, &c., in musical pieces, are marked with extreme accuracy, and should the parts of the music be deranged by a defect in time, an uneasy jog will be produced in the auditory apparatus, hence the antipathy of the mind to any erratic deviation in this respect. It is very remarkable that the *malleus* and *incus* (the hammer and the anvil) should correspond not only in figure, but also in function, to the objects from which their respective names are derived, for as we have already seen, the uses of the hammer and anvil, as employed in mechanics, are literally fulfilled by the *malleus* and *incus* answering very important ends in the faculty of audition. By the action of one upon the other, sounds are not only correctly transmitted to the auditory centre, but an accurate register of time, grace, and style, is effected in the manner above explained. Thus the physical organisation itself may be shown to be the natural preceptor of the mind.[1]

[1] Dr. F. de Chaumont writes as follows:—

Since Dr. Macdonald's paper was forwarded to you the appearance of Mr. Blyth's has added still stronger confirmation to the analogy between the microphone and the auditory apparatus of the mollusca, &c. One point in particular is the necessity of moisture of some kind or other, as a medium between the conducting particles, shown by the fact that even the watery vapour from the breath of the experimenter produced a sensible increase in the strength of the sounds elicited; and further, that the addition of simple water to the cinders was productive of still more striking effects. All this bears out the view taken by Dr. Macdonald that we have in the *otoconia*, *endolymph* and *vestibule* of the ear the most complete type of a microphone.

It would be well to try the free suspension of good conducting particles in a non-conducting fluid medium, sufficiently limpid to offer the least possible impediment to their movement.

The oscillation of the transmitter as a whole by mechanical means ought also to be tried in order to imitate the effect of vibratile cilia in the case of the auditory vestibule of animals.

F. de Chaumont

Army Medical School, Netley, June 20

WORK AND PROGRESS OF THE IMPERIAL GEOLOGICAL INSTITUTE OF VIENNA[1]

I. *THE Staff* has its full complement. M. D. Stur has been appointed sub-director, Dr. O. Lenz has returned from Africa with much information on the West Coast. M. Pilide, volunteer since 1875, has been appointed official geologist in Roumania. Two volunteers have joined, and there are four students in the museum and laboratory.

II. *The Building* has been considerably altered and enlarged, giving more space for laboratory, library, and museum.

III. *The Survey Operations* have been directed to (1) *the Special Map of the Empire.* Section 1. MM. Stache and Teller surveying the Central Alps south and east from the Cividale massif, the Oetzthal massif, &c. 2. MM. von Mojsisovics, Vacek, and Bittner—the Cima d'Asta, Sette Communi, and eastward to the Venetian plain, the Tertiaries of the Vicentin, and down to the valley of the Adige. 3. MM. Paul, Tietze, and Lenz, East Galicia and part of N.E. Hungary.

(2). *Local Surveys, &c.*, D. Stur—Review of Sternberg's and Corda's collections of Carboniferous Plants in the Prague Museum; Coal-bed of Upper Silesia; Fossil Plants of Lunz in Upper Austria. Stache—Palæozoic Schists of the Semmering on the Styrio-Austrian frontier. Von Mojsisovics—Trias in Upper Austria and Carinthia. Wolf—Railway Line in Upper Austria. Paul and Fr. Ritter von Hauer—Coal-beds of Aspang and Kladno. Bittner—Geological Map of the Archduke Leopold's Estates South of Vienna.

(3). *With Government Aid*, R. Hoernes—Devonian Strata near Gratz, Styria. Koch—Rhæticon and Selvettra group.

(4). *The Bohemian Commission.*—Krejci and Helmhacker—The Silurians of Central Bohemia. Laube—The Erzgebirg between Bohemia and Saxony. Fritsch—Palæozoic Saurians and Crustacea of Beraun. Nowak—Cypris-shales with Insects. Boritzky—Porphyries.

5. *Hungarian Geological Survey.*—Banat and South and West Hungary, surveyed by MM. Hofmann, Roth, Matiasovics, Boeckh, and Hantken.

IV. Rearrangement of and additions to, the *Museum.* Forty-one donors. Above 1,000 specimens, presented by Fr. Karrer, illustrative of the geology and fossils of the region traversed by the Francis-Joseph Aqueduct from the slopes of the Schneeberg to Vienna.

V. *Library.*—1. *Books:* Increase of 270 works in 281 volumes or parts; Periodicals, 422 volumes. Total at the close of 1877, 8,346 work in 22,496 volumes or parts; 766 Periodicals and Transactions in 13,261 volumes or parts. Various new Exchanges. 2. *Maps:* Arrangement completed. Total at the close of 1877, 933 in 3,825 sheets, besides the original maps by the Institute, and the special general maps of the Austro-Hungarian Empire reduced from them.

VI. *Laboratory.*—Newly established in a fresh locality. Enlargement of collection of artificial crystals, by Karl Ritter von Hauer. Analysis of eruptive rocks of the Ortler mountain-group, by M. John. Analyses of fossil fuel, ores, building-materials, &c.

VII. *Publications.*—1. The Transactions, vol. vii. part IV., and vols. viii. and ix., with fifty-four maps, sections, and plates, comprising Vacek's paper on the Mastodons of Austria; F. Karrer's Geology of the Francis-Joseph Aqueduct; and Stur's description of the Culm-flora. 2. The Annals: Ten contributors. 3. The Mineralogical Communications; Twenty-two contributors. These papers will for the future be published by themselves. 4. The Proceedings: Twenty-six contributors. 5. Other publications: MM. von Hauer and Neumayr's Guide for the Meeting of the German Geologists; M. Stache's Geological Map of the Maritime region of Austria; Fr. von Hauer's "Geology," second edition.

[1] From Fr. Ritter von Hauer's Annual Report, January 8, 1878.

METEOROLOGICAL NOTES

DR. OTTO KRÜMMEL publishes a paper in the current number of the journal of the *Gesellschaft für Erdkunde* of Berlin, on the distribution of the rainfall of Europe, illustrated by a well-executed map of seven colours, which show the regions where the annual rainfall does not exceed 9·8 inches (25 ctm.), is from 9·8 to 15·7 inches, from 15 7 to 21·7 inches, &c., the deepest tint covering all those regions where the rainfall exceeds 39·4 inches (100 ctm.). The map exhibits in a striking manner the small rainfall in the east and the heavy rainfall in the west; the markedly reduced rainfall of such mountain-sheltered plains as those which surround Paris, Clermont, Mannheim, Prague, Pressburg, and the great plain of Hungary; the large rainfall of the slopes of the Caucasus, which stands out in strong contrast with that of the arid regions all round; and the exceptional rainfall of Spain, which presents on the map a picturesque patchwork of all the seven colours representative of the wettest down to the driest regions portrayed on the map. The most important feature, however, is the partition of Europe into two divisions, by a waved line lying about the forty-third degree of latitude, the southern division being characterised by a rainless or all but rainless summer, and the northern by rain all the year round, where an absolutely rainless month is of rare occurrence. Slight exception may be taken to the rainfall set down for Iceland, Holland, and portions of the east of Scotland and west of Norway, as being a little too large, but on the whole the map is an admirable piece of work.

DR. HORNSTEIN, of Prague Observatory, has discussed the observations of the wind made there from 1849 with a Kreil's anemometer, and the results, which have been communicated to the Vienna Academy, disclose periodicities of velocity and direction generally accordant with Wolf's relative numbers of the sun-spots and with the well-known secular variation of the aurora. The mean annual velocity increases from the period of minimum to that of maximum sun-spots, and thence decreases with the diminution of the sun-spots to the minimum; and from the period of maximum to that of minimum sun-spots, the mean annual direction of the wind changes from a westward to a more southerly direction, while the change is in the opposite direction from the minimum to the maximum sun-spot period.

MR. BLANFORD, the Government Meteorologist for India, published quite recently a forecast of the weather of the monsoon season now set in. Reasoning from the unusually persistent high pressure then prevailing over Northern India, the singular absence of abnormal variations of pressure over the same region, and the heavy rainfall during the cold weather, he thinks it probable that the monsoon current will be below its average strength, that the rainfall will be more equally distributed than last year, and that the monsoon will commence later than usual in Upper India.

ON the occasion of the commemoration of the 400th anniversary of the founding of Upsal University in September last, the Swedish Government published an Atlas of fifty-one maps which had been prepared by Prof. Hildebrandsson to show the direction of the upper currents of the atmosphere during 1875 and 1876. About the same time the Meteorological Society (London) published thirty weather maps for March, 1876, prepared by Mr. Clement Ley, in illustration also of the upper currents. As regards the broad results arrived at, both authors are substantially agreed, the results being that while the surface winds blow inwards upon cyclonic areas

of low pressure and outward from anticyclones, the upper currents blow away from cyclonic and inwards upon anticyclonic areas. The most striking part of Mr. Ley's paper is the diagram in which he has summarised with no small amount of skill the facts of his cirrus-cloud observations. The point in the diagram is this: if the upper currents there depicted are to be regarded as tolerably close approximations to the movements of the cirrus-clouds of a cyclone, it follows that the region of the cirrus occupies a much higher level over the front portion of cyclone than it does over its rear—notably than over the north-west quadrant—a point of prime importance in relation to the theory of storms.

THE energetic way in which the Missouri (U.S.) weather service is being conducted may be judged of from the fact of the Report of the weather of May having reached us by post on June 24. This Report gives a statement of the rainfall for the month at from sixty to seventy stations, a map showing the distribution of the rainfall over the State for May, and a rapid sketch of the chief features of the weather. The rainfall was greatest in the central-southern districts, amounting to 8·00 inches at Bolivar, and least in the north-east, where at Canton it was only 1·77 inch. The increased efficiency of the system is well shown by the fulness with which the great storm of the 17-18th with its accompanying thunder and lightning and locally-developed whirlwinds has been accurately observed over Missouri, of which Director Nipher promises a full report. A separate sheet accompanies the Report, with all the instances of heavy rainfalls which have occurred during the past thirty years. Of these the most noteworthy as regards rate of fall was a downpour of 5·05 inches in an hour and-a-quarter on August 15, 1848. The heaviest continuous fall was 7·83 inches during thirty hours on June 18-20, 1859.

WE learn from the Mauritius Meteorological Report for 1876 that the rainfall of the whole island during that year was 12·63 inches less than the average, and that daily observations are now received from Seychelles, Rodrigues, and others of the neighbouring groups of islands. Valuable tables appear in the Report, showing the monthly means of pressure, temperature, and humidity from 1853 to 1874; but the noteworthy feature of the year's observations are the mean hourly values of the velocity and direction of the wind now published for the first time. These exhibit a well-marked daily period in the direction from E. 22° 15′ S., the most southerly point at 4 A.M., to E. 7° 0′ S. at 1 P.M., and thence back to E. 22° 15′ S. at 4 A.M., the daily variation thus being 15° 15′. Equally marked is the diurnal variation in the velocity, the minimum 9·7 miles per hour occurring from 2 to 3 A.M., and the maximum 18·5 miles per hour from 1 to 2 P.M. Hence, as regards this part of the south-east trades, the influence of the sun during the day is to double the velocity of the wind and to impress upon it a more truly easterly direction.

IN an eighth contribution to meteorology Prof. Loomis deals with the origin and development of storms, in which he shows that the great American storms are not confined in their origin to any particular locality, half of them originating on or close to the Rocky Mountains, and more than two-thirds north of 36° N. lat. The first stage in their development is the formation of an area several hundred miles in diameter, over which the barometer differs little from 30·000 inches, with areas of high barometer on the east and west sides, often another to the north, and occasionally a fourth to southward. The mean height of these different high areas examined was 30·310 inches on the west and 30·420 on the east side, that on the east side being thus the greater; and the distance of each from the central area of nearly uniform pressure which they surround is generally about 1,000 miles. A system of winds towards an intermediate or central point then sets in, resulting in a diminished pressure over the central area. The author supposes that the inflowing air escapes by an ascending current, carrying with it a large amount of vapour which as it is cooled is condensed into cloud and rain, and that the heat thus liberated further expands the air, thereby increasing the force of the inward movement of the wind. Rain is thus one of the conditions which increase the force of a storm. Prof. Loomis finds that an area of low barometer of considerable size may be formed and continue for several days with little or no rain, but in such cases the pressure did not fall so low as 29·250 inches. No storm of great violence has yet been found unaccompanied by a considerable fall of rain or snow. The general inward movement of the air towards a central area begins before any considerable precipitation of rain or snow has taken place. The easterly course of storms is considered to be occasioned by the general circulation of the atmosphere in that direction, and by the upward motion of the air taking place principally on the east side of the low centre as indicated by the position of the rain-areas. By this upward motion the air which presses in upon the east side of the low centre is prevented from restoring the equilibrium of pressure upon that side, and thus the low centre is steadily transferred toward the east, or the storm travels eastward. On the other hand, when the fall of rain or snow on the west side of the low centre is copious, widespread, and continued, the easterly progress of the storm is retarded, or arrested, or in some cases even retrogrades to westward, of which the storms of March 9-14, 1874, and January 1-18, 1875, were examples.

DR. WOJEIKOF sends to the Paris Exhibition new isobaric charts of the globe for January and July, which are rectifications of Buchan's isobaric charts, published in 1869, made by charting the large amount of fresh and fuller meteorological information collected since that time. Lake Baikal has recently been levelled, and its true height now ascertained to be 1,539 feet above the sea, instead of 1,342 feet, as given by Kropotkine. Correcting the barometrical observations for this height the mean pressure of this region in January is 30·630 inches, which is the maximum mean pressure for the globe at this season, and consequently 0·200 inch greater than was given in Buchan's chart. This extraordinarily high pressure in Eastern Siberia, which is 1·300 inch higher than that of Iceland at this season, is attributed by Dr. Wojeikof to the clear dry atmosphere of Siberia, and intense cold of the valleys and the high mountain barrier, which shuts off all communication, as regards the lower atmosphere, with the Pacific, where pressure in winter is low. A point of some interest brought out in the chart for July is the existence of two centres of low pressure controlling the wind systems of the Asiatic continent, the one being the Punjab and adjacent parts of Beloochistan, and the other the region around Lob-Nor. Dr. Wojeikof introduces an important feature into his charts in *not* tracing the isobaric lines over those portions of the globe which are at least 1,800 metres (5,906 feet) above the sea, some mountain-groups only being excepted. In this way the great plateau of Tibet, with its ramifications, is omitted, it being evident, for instance, that the winds of the Gangetic plains cannot be influenced by any differences that may obtain between the sea-level pressure there and that of the plains of Siberia, owing to the high, broad plateau of Tibet interposed between.

GEOGRAPHICAL NOTES

IN the course of the address which he recently delivered before the Geographical Society upon the subject of his travels on the western frontier of China, Capt. W. J. Gill, R.E., gave an interesting account of

his experiences on the borders of Thibet. He entered that land of mystery at Ta-chien-lu, whence the road at once ascends to the great plateau through a valley amongst granite rocks, capped at the summit with bare crags of limestone. Standing on the summit of the pass, by which the great upland country was reached, the traveller saw stretched below a fine valley closed in on both sides by gently sloping round-topped hills, covered with splendid grass. The road to Lithang was a succession of mountainous valleys, huge pine forests, and open glades. Capt. Gill found Lithang a cheerless place, some 12,500 feet above the sea-level. The natives told him that Ta-so, the last mountain-pass before reaching Bathang, was a very bad "medicine-mountain," the inconvenience caused by the rarefaction of the air at these great altitudes being attributed by them to subtle exhalations. On the road thither Capt. Gill passed the magnificent mountain Nen-Da, 22,000 feet high, and near the top of Ta-so he entered a little circular basin, surrounded on all sides but one by ragged precipices, with a pond of clear water at the bottom. On crossing the crest of the pass, he entered a large basin two miles in diameter, where a wild and savage scene presented itself to his sight: great masses of bare rock rising all round, torn into every conceivable shape by the rigour of the climate. The bottom of the basin was covered with the *débris* that had fallen from them, and some small pools of water in the hollows formed the sources of the stream, which eventually became a roaring torrent among the pine forests in the valleys below. Bathang, Capt. Gill found, had been recently rebuilt, after its destruction, a few years ago, in a frightful series of earthquakes, which, lasting for several weeks, devastated the whole neighbourhood. The town, he says, is chiefly remarkable for its immorality and its lamasery. Besides his description of the country Capt. Gill gave some interesting information respecting the habits of the Thibetans, contrasting them with those of the Chinese. Owing to their originally nomad mode of living they have no idea of inn accommodation, and the owner of a good house even will, as often as not, be found sleeping on the flat roof, whilst the hardy people in winter can sleep with their clothes half off and their bare shoulders in the snow; tables, chairs, and bedsteads are unknown in their houses. Thibet is a land flowing with milk and butter, the enormous quantity of the latter consumed by a Thibetan being very startling—butter in his oatmeal porridge, and huge lumps of butter in his tea. As a rule he does not drink much milk, which is mostly made into butter, but he is fond of sour cream, curds, and cheese; and this brings a Thibetan bill of fare to an end.

NEWS from Samarcand recently received gives some interesting descriptions of the district of Karatejin, which formerly belonged to Khokand but was afterwards ceded to Bokhara by the Russian Government. Karatejin, with the smaller districts of Dorwas, Waghia, and Shugnan, as well as the largest portion of Kojistan, are situated in the immediate neighbourhood of the plateau of Pamir. Karatejin in winter is completely isolated, and only during the summer months is accessible from the neighbouring districts. The manners and customs of its inhabitants are yet in the most primitive state. They have no idea of measures or weights, have neither markets, booths, caravans, nor indeed any institutions of public life. Theft is a thing unknown amongst them. Their occupation consists mainly in tending cattle, besides a little agriculture; everything is general property, as it were. If any family is short of provisions it is a matter of course that the next neighbour gives them what they may want.

THE *Pandora*, which is to be sent out by the *New York Herald* to the North Pole, has been re-christened at Havre the *Jeannette*. She leaves this week for San Francisco to complete her outfit, and starts next June for Behring's Straits. News has been received from Washington that there is no probability that funds will be appropriated this year for the intended Polar Colony of Capt. Howgate. No tidings have arrived yet from Capt. Tyson's preliminary expedition.

A CORRESPONDENT of the Hong Kong *Daily Press*, writing from Labuan, gives some interesting particulars respecting a scheme which, if carried out, may contribute much to the development of the resources of Borneo. An American company was formed for this purpose some time back, and obtained large concessions from the Sultan; but the policy of the United States government being to discourage in every way the extension of American commerce abroad, and the expenditure of any capital in foreign countries by its citizens, it has been deemed expedient to transfer the rights thus acquired to British merchants, and to leave to them the task of developing the enormous riches which now lie dormant in this beautiful island. For this purpose the steamer *America*, with representatives of both parties, went to Brunei, and the circumstances of the case having been explained to the Sultan, he not only consented to the transfer, but added to the former grants that of Gaya Island and the mainland opposite, including the magnificent harbour known as Gaya Bay, an enormous sheet of water said to be capable of sheltering the united fleets of the world. By this addition to the former grant the territory conceded now extends in an unbroken line from Kinarn's Bay, on the west coast, across the island to Sibuco, on the southern edge of St. Lucia Bay, on the east coast. This matter having been arranged, the *America* proceeded northwards, and, entering Maludu Bay, passed through the Malwalla channel to Sandakan. The approaches to this channel are very imperfectly surveyed, and abound with coral reefs and shoals not marked on the charts. From Sandakan the steamer went on to Sulu, and anchored in Membong Bay, about fifty miles south of the petty fort of Bhanuar, which has been held by Spain for the last two years. The Sultan of Sulu, when visited, expressed his hearty concurrence in any scheme which would tend to open up and civilise the rich and splendid provinces on the mainland now lying waste, and he at once confirmed the grants made by the Sultan of Borneo. Returning to Sandakan, the party proceeded up the Kina Batangan River in a steam launch, penetrating nearly two hundred miles into the interior, where no European vessel had ever been before, and then, having taken formal possession of their property at Sandakan, proceeded on their voyage to Labuan.

THE Rev. W. G. Lawes, the well-known New Guinea traveller and missionary, has communicated to the *Colonies* an interesting account of a visit which he paid, towards the close of last year, to the previously unknown village of Kalo, on the western bank of the Uanekela (or Kemp-Welch) River, which empties into Hood Bay, New Guinea, not far from Kerefunu. Mr. Lawes says that the village is laid out in streets and squares, all of which are kept scrupulously clean, being swept every day by the women. He induced one of the chiefs to accompany him some three miles up the river, which he found takes a sharp curve a little way above Kalo, and becomes narrower, but after about a mile it widens out again into a fine broad stream. It is said to be navigable for a long distance, and, according to native accounts, runs to Manumanu, in Redscar Bay. On the Kalo side of the river groves of cocoa-nut trees abound, and betel-palms are also plentiful, while on the east bank numerous and extensive plantations of bananas and sugar-cane were seen. Mr. Lawes states that the villages round and near Hood Bay are inhabited by a fine race of men, who are industrious and kindly-disposed, though at first shy and suspicious. They have a warlike character, but their hostility to each other would probably be soon removed

if more constant intercourse were established among them. Cocoa-nuts are at present the only article of any commercial value which the natives possess, and it is probable that some day large quantities of *copra* will be exported from this part of New Guinea; no doubt, too, the country has other resources which are as yet undeveloped.

NOTES

IN reference to our article (vol. xviii. p. 235) referring to the very unsatisfactory manner in which the publications of the Geological Survey are produced and distributed, we have received several communications professing to indicate the causes to which this unfortunate condition of affairs is to be attributed, and suggesting means by which it can be remedied. It would scarcely be within our province—even f it were in our power—to point out the particular departments or the individual officials with whom the responsibility for bringing about this almost perfect deadlock rests. We do, however, feel ourselves called upon to give expression to that dissatisfaction which is so widely felt in scientific circles, both in England and abroad, at the slowness with which the survey is carried on, the dilatoriness with which its results are published, the exorbitant prices charged for the maps and memoirs, and the parsimonious manner in which they are distributed. And in doing so we are acting no less in the interest of the overworked and often underpaid officers of the survey, whose efforts are frequently wasted, and whose patient labours fail to obtain proper recognition, through the neglect of the publishing department in making known the results of their work.

AS an instructive comment on the above, we may state that we have just received a magnificent series of maps illustrating the geology of Wisconsin and Colorado, along with a thick descriptive volume relating to the former state, full of beautiful chromo-lithographic illustrations of the peculiar geological phenomena to be found in the state. In execution and scientific accuracy these maps are equal to anything of the kind we have seen produced in Europe, and their liberal distribution by the Central and State Governments ought to make our own Government ashamed of its "penny-wise and pound-foolish" parsimony. The Colorado maps are issued, under the care of Dr. Hayden, by the Department of the Interior, while the Wisconsin volume and maps have the names of Messrs. Chamberlin, Irving, and Strong attached to them.

DR. JANSSEN has succeeded M. Puiseux in the astronomical section of the French Bureau des Longitudes, thus leaving vacant the post of geographer to the Bureau.

AT its session of July 1, the French Academy of Sciences elected Prof. C. Friedel to the vacancy in the chemical section resulting from the death of V. Regnault in January last. His chief competitors were MM. Cloez and Schutzenberger. Prof. Friedel occupies the chair of mineralogy at the École des Mines. His time is devoted, however, chiefly to chemical research, and he is at the present day the most prominent representative of the modern school of French chemists, who have grown up under the eye of Prof. Wurtz. His activity as an investigator began in 1856, and since that time he has chronicled a large number of valuable results won in various departments, but more especially in organic chemistry. His name is associated chiefly with extensive and elaborate researches on acetones, and on silico-organic compounds, and with the remarkable series of syntheses in the aromatic series by means of aluminium chloride, which for some time past he has been carrying out in company with Prof. Crafts, of Boston. Although his hair is streaked with grey, Prof. Friedel possesses a vivacity, energy, and devotion to his science, unexcelled by any of the younger chemists of the day, and promising a long-continued activity in the future.

AMONG recent deaths abroad we notice those of Prof. J. L. Chateau, of Ivry-sur-Seine, Prof. Labat of Bordeaux, and Prof. Ehrmann, formerly Dean of the Medical Faculty of Strasburg, who was aged eighty-six at the time of his death.

PROF. VIRCHOW is following up the cranial investigations which led him to assign a Turkish rather than a Slavic origin to the Bulgarian race. For this purpose he has recently received fifteen Bulgarian skulls from the battle-field of Kadikiöi, which have been carefully prepared by the red-cross surgeons.

PROF. VIRCHOW has decided to resign his seat in the German Parliament. He takes this step solely because his parliamentary duties interfere with his scientific labours; and, while he may be a good enough politician, he thinks himself a better *savant*.

WE briefly alluded recently to the annual session of the Vienna Academy of Sciences. At this session Baron von Rokitansky was re-elected president for the coming year, and the Crown Prince Rudolph of Austria was named honorary member. The class for mathematics and natural sciences has lost by death during the past year among its regular members K. v. Littrow, and among the corresponding members, the astronomer, Santini, of Padua, and the physicists Weber and von Mayer. These vacancies were filled by the election of Prof. E. Weiss of Vienna to Littrow's chair, and by the election to corresponding members of the zoologist, Prof. v. Brauer, of Vienna, the physicists, Prof. G. T. Fechner, of Leipzig, Sir William Thomson, of Glasgow, and Prof. J. Schwann, of Lüttich. The triennial prize for the most fruitful contribution to physics was assigned to Capt. A. von Obermayer, for his researches on the influence of temperature on the friction coefficients of gases. Prizes for the discovery of comets have likewise been assigned to MM. Winnecke, of Strassburg, Coggia, of Marseilles, Tempel of Florence, and Swift, of Rochester, New York. The Academy has appointed during the past year a standing committee for ethnographical researches in Austria. Prof. Doelter, of Graz, who was recently sent by the Academy to make a study of the extinct volcano, Monte Ferru, on the island of Sardinia, has recently submitted to the academy a detailed report of his investigations. The analyses of the lavas would tend to place them among the more modern eruptive formations. Monte Ferru exhibits a variety in the character of its lava deposits rarely found among volcanoes thus far examined. The chief species described are normal phonolite, trachytic phonolite, sanidine-plagioclase trachyte, sanidine-augite trachyte, felspar with and without olivine, leucite-basalt, trachyte,-tufa, rhyolite and hornblende-andesite.

ARRANGEMENTS are being made in Paris for an interesting sequel in 1879 to the present exhibition, which shall be entitled "Exposition des Sciences appliquées à l'Industrie." It will occupy the old Palais de l'Industrie. Assurances of co-operation on the part of leading scientific and industrial personages have been so numerous, that the success of the undertaking is already well guaranteed. The programme defining the aims and limits of the exhibition will appear at an early date.

THE *Medical Times and Gazette* regrets to learn that Dr. Burdon Sanderson has resigned his post as Professor at the Brown Institution. The work he has done in this position has been of a kind that is above praise. It has been mainly directed to the investigation of the phenomena of contagion, and, coupled with that of Dr. Klein, also connected with the Brown Institution, has done much to instruct us in the structure, functions, and characteristics of the lymphatic system—to mention only one series of researches. We sincerely hope that the post will be filled by one who will continue and expand the work already commenced in this invaluable Institution.

THE new historical museum of Frankfort-on-the-Main was opened on June 14. The new museum now contains all the objects of antiquity and art which were hitherto distributed in various public buildings of the old city. Several local scientific societies have presented the whole of their collections to the new establishment.

THE foundation stone of the Chadwick Natural History Museum was laid last week. The building is to be in the public park, Bolton. At present the town, although the third in importance in Lancashire, does not possess a museum.

A LETTER from the Préfet de la Seine has been sent to M. Mascart, the Director of the French Central Meteorological Bureau requesting that arrangements be made to post the weather warnings at the Bourse, Pont St. Eustache, and Halles Centrales, three places where monumental barometers have been placed at the expense of the municipal exchequer. It is curious that Paris does not yet receive a single warning although warnings are sent daily to 1,500 parishes, most of them of the smallest description.

THE first number of *L'Electricité*, a French semi-monthly periodical, has been issued.

A GENERAL meeting of the Mineralogical Society of Great Britain and Ireland was held at 116, Victoria Street, S.W., on Thursday, July 5, R. H. Scott, F.R.S., in the chair. Prof. Harkness read a paper on "Cotterite," a new variety of quartz from Ireland. A paper by Prof. Heddle, of St. Andrews, on "A New Manganesian Garnet from several Localities in Scotland," was read by the Secretary. The Secretary also read papers on "Youngite," and on "The Artificial Production of Psilomelane," communicated by Mr. J. B. Hannay, of Owens College, Manchester; and on "Penwithite, a New Cornish Hydrous Manganesic Silicate from Cornwall," analysed and described by himself. The annual meeting was fixed for Wednesday, August 14, at 2.30 P.M., to be held at Dublin.

BESIDES those whose names we gave last week, Mr. A. Cowper Ranyard, Mr. F. C. Penrose, and Mr. Giles Loder have also sailed for America, to observe the eclipse of the sun on the 29th inst.

WE have received the July number of the *Pantiles Papers*, a monthly literary magazine and review published at Tunbridge Wells. We are glad to see that the journal pays some attention to science.

TWO aeronautical ascents have been made from the Paris Cour des Tuileries in balloons of 450 cubic metres filled with hydrogen gas; the first took place on June 30 by MM. Gaston Tissandier and Jules Godard, and the second on July 7 by MM. de Fonvielle and Albert Tissandier. Both balloons were guided by a N.W. wind. On July 7 the balloon travelled at a regular rate of nine metres per second. Some interesting observations were made. It was noticed that cumuli have a height sometimes twice as great as their horizontal dimensions. The summit was observed to reach an altitude of 3,500 metres when the base was floating at an altitude of 800 metres. These clouds play the part of humid conductors connecting inferior with superior strata, and their dissolution in the form of rain is connected with electric phenomena.

MR. BRYCE M. WRIGHT has reprinted in a separate form from the *Journal de Conchyliologie* his "Description of the New Genus *Delphinulopsis*, and of the New Species *Delphinulopsis lesourdi*."

THE Paris Jardin d'Acclimatation has just made a most extensive and valuable acquisition of animals from Nubia. It includes fourteen giraffes, seven elephants, ten lions, two young hippopotami, seventy dog-faced baboons, and a number of antelopes, panthers, birds, &c. Herr Reiche, of Hanover, who captured these animals on the banks of the White Nile, receives for them the sum of 10,000*l*.

THE ancient records of the monastery of Fulda, and other German cloisters, which have been recently published among the *Monumenta Germaniæ*, give detailed accounts of a visitation of grasshoppers in the year 873, surpassing in point of destructiveness even those prevalent of late years in America. The grasshoppers appear to have come from the East, and, after having devastated nearly the whole of France, perished in the Atlantic. They are described as having hidden the sun, and having been able to eat everything green on a hundred acres in the course of an hour. Spanish monastic archives relate likewise the appearance of grasshoppers in 873, which appears to be the first record of an invasion by these insects in Europe.

WE are asked to state, on behalf of the Sunday Society, that, through the praiseworthy liberality of Sir Coutts Lindsay, the proprietor and director of the Grosvenor Gallery, New Bond Street, the Summer Exhibition at this institution will be open on the three following Sunday afternoons, between the hours of two and six:—On Sunday, July 14, the gallery will be opened free to the subscribers and members of the Sunday Society, and on July 21 and August 3 to the public, by tickets, which will be issued by the Sunday Society. These will be forwarded by post on receipt of stamped envelope. All applications to be by letter to the Honorary Secretary, 19, Charing Cross.

WE give the following extract from a letter sent us by Mr. R. Chartres on recurring decimals of the form—

$$\cdot\dot{a}\, b\, c \,..\, k\, a_1\, b_1\, c_1 \,..\, \dot{k}_1, \text{ where } a + a_1 = 9 = b + b_1 = \&\text{c.}$$

$$\tfrac{1}{19} = \cdot\dot{0}5263157894736842\dot{1}.$$

Here we observe a remarkable connection between the figures. Beginning with the last figure 1 we notice that each figure is double of the one to the right of it, one being carried when the double is over ten. Thus the eighteen recurring figures can be written down in a moment. Similarly the twenty-eight recurring figures of $\frac{1}{29}$ can be written down at once by multiplying by 3, thus:—

$$\tfrac{1}{29} = \cdot\dot{0}34482758620689655172413793\dot{1}.$$

Generally,
$$\frac{1}{nr - 1} \text{ (where } r = 10)$$
$$= -1 + \frac{nr}{nr - 1} = -1 + \frac{1}{1 - \frac{1}{nr}}$$

= Sum of the terms after the first of a geometric series *ad infinitum* whose first term is unity and common ratio $\frac{1}{nr}$.

Now, to divide a decimal by nr is simply to divide by n, and remove the figures one place to the right; and since the last recurring figure will be unity, we can get the whole period by beginning with 1, multiplying by n, and placing it to the left.

M. BOREL, the French Minister of War, has prepared a decree, which has been signed by the President of the Republic, for establishing in the army a high school of war. Besides tactics and special lectures on military topics, pupils will be taught geodesy, topography, geography, and telegraphy. They will be taken from among officers who have been commissioned for some length of time.

ARTICLE No. V. of the third volume of "Hermathena" is an exceedingly able and interesting sketch of "Greek Geometry from Thales to Euclid," by Dr. G. J. Allman. At the outset it is stated that the present century is "characterised by the importance which is attached to historical researches, and by a widely-diffused taste for the philosophy of history." In mathe-

matics Dr. Allman points to such works as Bretschneider's "Die Geometrie und die Geometer von Euklides"; Hankel's "Zur Geschichte der Mathematik in Alterthum und Mittel-Alter" (we are glad to find that our author's opinion of this work harmonises with the judgment we ventured to pass upon it in these columns); to Hoefer's "Histoire des Mathématiques" (1874), and to some others with which we are not acquainted. Dr. Allman opens his remarks with stating that "in studying the development of Greek science, two periods must be carefully distinguished. The founders of Greek philosophy—Thales and Pythagoras—were also the founders of Greek science, and from the time of Thales to that of Euclid and the foundation of the museum of Alexandria, the development of science was, for the most part, the work of the Greek *philosophers*. With the foundation of the school of Alexandria, a second period commences; and henceforth, until the end of the scientific evolution of Greece, the cultivation of science was separated from that of philosophy, and pursued for its own sake." In the course of forty-seven pages the investigation of what discoveries and advances are due to each geometer is most carefully and discriminatingly done, and the reader is put in full possession of the several authorities, and is thus in a position to try the correctness of Dr. Allman's deductions. We shall look forward to the continuation of the present paper which the writer promises.

AT a recent meeeing of the Birmingham Microscopical and Natural History Society, Mr. A. W. Wills exhibited the curious rotifer *Melicerta pilula* (figured by Mr. Charles Cubitt in the *Monthly Microscopical Journal* of July, 1872), which coats its tube with a wall of pellets consisting of *its own excremental pilules.* Mr. Wills gave an interesting description of the rotifer, and of his experiments with it. One of the specimens he exhibited had commenced the wall of its tube with the natural pellets, and had finished it first with blue pellets, and lastly with scarlet, according as he had fed it with indigo and carmine. After the meeting Mr. Wills gave the remainder of his specimens to Mr. Bolton for distribution among his correspondents.

IT is stated on the authority of a native Japanese paper, that the Hakubutsu Kioku (Exposition Bureau) of the Home Department proposes to erect a permanent exhibition building at Uyano, on the site of the National Exhibition held last year. It will cover about 700 tsuba of ground, and the frontage is to be 360 feet by 75 feet. On its completion it is intended to close the exhibition at Yamashita.

DR. MANZONI, of Bologna, has recently established the identity of the marl deposits of Upper Austria with those of the Renodale near Bologna, and describes eight varieties of echinoderms common to the two formations. Of these one still exists, and another is likewise found in chalk deposits.

THE philosophical faculty of Göttingen has offered two prizes of 1,700 and 680 marks for the best works on the causes affecting the changes in chemical composition of plants of the same species, such as climate, soil, fertilisation, &c. They must include a critical review of all facts hitherto gathered on this subject, and suggestions as to the best methods for completing our knowledge in this department, accompanied by the results of independent research in the directions indicated. Competitors must forward their work before August 31, 1880, and the decision will be announced March 11, 1881. They can make use of Latin, German, French, or English.

W. LANGE has sought to answer the question whether the silicium present in the sap of plants is in the form of silico-organic compounds, or not, and finds (*Ber. d. deutsch. chem. Gesell.*, vol. ii.) that it exists exclusively as a hydrate of silicic acid in very dilute solution.

FURTHER RESEARCHES ON THE SCINTILLATION OF STARS

THE results at which M. Ch. Montigny had arrived with regard to the influence of the atmosphere upon the scintillation of stars (see NATURE, vol. xiv. p. 562) have since been thoroughly confirmed by his further researches on this subject. The series of observations now comprises no less than 447 evenings, and the predominant influence of rain upon the intensity of scintillation may now be recognised as proved beyond doubt. We may here remind our readers that the intensity of scintillation is measured by the number of changes of colour which the star shows in the scintillometer during one second, and that M. Montigny has first proved that approaching moist weather increases this intensity. The frequent occurrence of wet days in the year from August, 1876, to August, 1877, has increased the average intensity from 71 to 76; but the following very dry autumn of 1877 brought down the average to 68 for that season.

M. Montigny has also given continual attention to the relation between the scintillation and the nature of the spectrum of any particular star. He has, as before, classified the 41 stars observed according to the three types of Father Secchi (of which type I. comprises the stars with four lines in the spectrum, type II. those with a number of fine lines or indistinct bands, and type III. those with broad bands and black lines), and for each type the new average intensity of scintillation is now given, each star in these comparative researches being reduced to an altitude of 60°. It appears now that the average for the first type has remained exactly the same as found before, while those for the other two types have changed but very little, although the number of observations has now risen from 611 to 3,025. These slight changes arise, doubtless, from the circumstance that the recent observations extend to 108 stars instead of 41. All these observations confirm, in the most definite manner, that fact which has already resulted from the first observations, and which M. Montigny expresses as follows:—"The stars possessing spectra with dark bands and black lines scintillate less than those with fine and numerous spectral lines, and considerably less than those possessing spectra with but a few principal lines."

Reserving the special data regarding the scintillation-intensities and the details of the stellar spectra for a further communication, M. Montigny now publishes a series of results respecting the colours of stars, which are of extreme interest.

The colours which the stars show in the scintillometer change in frequency from one type to another, and even between stars of the same type. For the same star the colours in their particular shades, in their frequency, and in their brightness, are further affected by temperature, the degree of atmospherical moisture, and the altitude of the star above the horizon. On the same evening, and under the most favourable atmospherical conditions, the number of colours and their brightness decrease steadily as the star rises in the east, and at a certain altitude they are no longer seen. In the west the reverse takes place, *i.e.*, the number of colours and their brightness increase the lower the star sinks, down to a certain altitude above the horizon, which changes according to the clearness of the atmosphere. If the star rises or sets, the limit at which the colours cease to be distinct is all the lower, both in the east and in the west, the finer and warmer the weather happens to be at the time. If the star has passed beyond this limit in rising or has not reached it in setting, it shows only a circle of a constant colour in the scintillometer, *i.e.*, of the colour peculiar to the star, and thus this apparatus offers an excellent means for determining the colours of stars.

The colours observed in scintillation are: red, orange, yellow, green, bluish green, blue, and violet. The difference in these colours is characteristic for the different star types, if we neglect the influence of the star's altitude and the condition of the atmosphere. Thus the red, which is the most constant colour for the three types, generally approaches the shade between the lines B and C of the solar spectrum in stars of the two first types, while stars of the third type give either a very dark red, or a bright cherry red, or very deep pink. The blue in stars of the first type is bright, and resembles steel blue in shade, while the blue in stars of the third type often shows a very dark shade, so dark sometimes that it becomes difficult to recognise it. When the weather was rainy the blue seemed generally to predominate amongst the other colours in all stars. Pure green was not so frequent than the other colours. Violet was also very rare amongst all the stars, but particularly amongst

those of type III.; if this colour was visible in stars of the other two types, they were always near the horizon. Yellow was rarely absent; yellow of greater or lesser brightness predominated completely in a large number of stars when they were high above the horizon and had ceased to scintillate. Orange is very frequent amongst the colours of the stars of the third type, while they scintillate.

If we reflect upon this short sketch of the changes of colour of scintillating stars, we see at once how complicated this phenomenon is, and that, in order to obtain data of tolerable certainty, at least two series of observations must be made, one in dry and the other in rainy weather; and further, that the influence of the star's altitude must be determined, which can be done by dividing the observations into separate zones of five degrees each.

With regard to the colours of scintillating stars Arago has expressed the opinion that the colour observed at any special moment is the complementary colour to those rays of the light peculiar to the scintillating star which at that moment are absent in the eye or in the telescope. M. Montigny agrees with this view and confirms it by an observation which he made when, on some evening specially favourable for observation, he inserted a prism just when the circle produced in the scintillometer by the light of the star Capella was very sharp and showed bright colours; he then found the two arcs of the circle divided into different colours, and this could not have been the case if the colours seen without the prism had actually been present. M. Montigny, however, intends further to examine this question by means of the spectroscope.

Arago also raised the well-known question whether the scintillation of stars is the same for two observers stationed at different places. M. Montigny replies to this question in the negative, and this was Arago's opinion also; he found the colours of a star to be different for those rays which are differently refracted by the two halves of the object-glass. In the same sense M. Donders has noticed that the scintillation does not always show the same peculiarities for each eye of the same observer. Another circumstance may be cited here as another proof, viz., that a double star, both components of which are of the same colour, such as Castor and its companion, which are both white, does not always show the same colours in the scintillometer at the same angles of position. Although the angle separating these two stars amounts to but five seconds of arc, it yet suffices to produce different colours. This shows how greatly the appearance of stars in the scintillometer is affected by the smallest differences in the conditions under which they are observed, since two separate pencils of rays of the same colour travelling side by side and at the same moment may yet be changed to different colours on their passage through the atmosphere.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

The subject of the use and abuse of examinations is beginning to be agitated in Austria. Within a few weeks past, two students, one at Pest and the second at Graz, have committed suicide after failing to pass examinations for the doctor's degree. The latter of the two had completed a lengthy course of study, and was an assistant of recognised ability in the university.

During the past few years the educational institutions of Rome have been entirely reorganised. The university, as constituted at present, is without a theological faculty. It numbers sixty-four professors, twelve in the legal faculty, twenty-four in the medical, sixteen in the scientific, and twelve in the philological-philosophical. Nearly all the conveniences of a well-appointed university are now enjoyed by the students: a botanical garden, laboratories for physics, chemistry, and physiology; the new observatory on the Capitoline, with special institutes for geology, mineralogy, mathematical physics, pharmacy, comparative zoology and anatomy, pathological anatomy, and six clinics. During the past month the Minister of Education has issued a decree for the foundation of a school of archæology, which shall be amply equipped, and meet a want long felt in this centre of archæological investigation.

SOCIETIES AND ACADEMIES

London

Royal Society, May 23.—"Experimental Results relating to the Rhythmical and Excitatory Motions of the Ventricle of the Heart of the Frog, and of the Electrical Phenomena which accompany them," by J. Burdon Sanderson, M.D., F.R.S., and F. J. M. Page, B.Sc., F.C.S.

This paper, although of some length, is a condensed statement of experimental results, so that it scarcely admits of being abstracted. These relate, as stated in the first paragraph, to (1) the order and duration of the rhythmical and excitatory motions of the heart of the frog, (2) the normal electrical condition of the surface of the heart and the influence thereon of mechanical, chemical and thermal injuries, and (3) the characters of the normal and of the excitatory electrical variations, and the modifications of those characters which are induced by injuries of the surface, and under the temporary influence of radiant heat. As we have not space to reproduce the whole, we will confine ourselves chiefly to the very interesting experiments contained in the two last sections.

The authors begin this part of the subject with the statement that they have confirmed, by repeated experiment, the observations made by Engelmann in 1873, that all parts of the surface of the "resting" heart are equipotential, and that the electrical inequalities which are usually found whenever the surface of the organ is investigated, when in this condition, owe their existence to slight injuries; they then proceed to discuss the conditions which lead to the existence of electrical differences. These are (1) permanent injury of the surface, however superficial and slight in extent, and (2) the temporary influence of radiant heat. As regards permanent injury, their observations are substantially in accordance with the conclusions of Hermann as regards other excitable and contractile tissues, viz., that the death of a part renders it *negative* to all living parts of the same organ. Substituting for the word death (which, in order to express the whole truth, must be understood to include every degree of local lesion, however limited in extent or slight in degree) the expression "permanent injury," this proposition becomes adequate for its purpose.

The authors further find that the influence of radiant heat produces a modification of the electrical condition of a part, of which the sign is opposed to that of the electrical change produced by injury. They were led to this result by the consideration that if arrest of the chemical changes which constitute the life of a part renders it negative, it is probable that a momentary intensification of these changes will render it positive.

The fundamental experiment by which both facts are established is as follows:—Two points on the surface of the heart, which may be as near to each other as two millims., are connected with a galvanoscopic circuit, and found to be equipotential. A loop of platinum wire, heated by a current, is brought into the neighbourhood of one of them for one second. After an interval of about a second the warmed surface becomes positive: in a few moments this effect subsides. If, then, the hot wire is brought nearer so as to scorch the surface, however slightly, and then removed, the opposite effect—that of permanent injury—manifests itself. The same spot, which was before positive, now becomes negative in a very much greater degree; for whereas the temporary "positivity" scarcely exceeds 1-2,000th Daniell, the "difference" of potential produced by injury may amount to 3-100ths Daniell. On the physiological meaning of these effects the authors do not enter. An indication of their bearing is, however, given by the observation in the next section, which relates to the so-called variation of the heart. By variation is meant the electrical disturbance which accompanies, or rather precedes, each contraction of the ventricle. The fact that such a disturbance exists has been known for several years. It has also been recognised that it precedes the visible change of form by which the systole discloses itself. The authors now show that the disturbance consists of two phases having opposite signs—that in the first phase, which is of short duration, parts near the apex become positive to parts further from it; that in the second phase the opposite condition is observed; further, that the first phase is entirely over before the ventricle begins its contraction, whereas the second phase corresponds in duration with the period during which the ventricle is doing the greatest amount of mechanical work, and ceases at the moment of decline of the muscular contraction of the ventricle. These time relations of the two phases suggest the inference that in all probability the first phase corresponds with that of the negative variation of ordinary muscle, with which it agrees in sign, and that the second phase is more immediately associated with the muscular contraction. That this is so appears to be shown by the observation that if any two points of the rhythmically pulsating heart a and b, of which a is nearest to the apex, are investigated by

suitable means during the period of systole, it is found that the variation observed (in which, so long as the surface is in its normal state, *a* becomes negative to *b* in the second phase) is modified by momentarily warming (in the manner already described) as follows:—When *b* is warmed *a* still becomes negative in the second phase; but the extent of the deflection is four or five times as great as before. When *a* is warmed, instead of becoming negative in the second phase, it becomes positive; in other words, the second phase is reversed. Permanent injury (as *e.g.*, by the closer approach of the hot platinum wire) produces similar results, with this difference: that whereas the modifications produced by radiation are transitory, and in fact pass off in a few seconds, those caused by injury are of much longer duration. All these facts seem to show that there is an intimate relation between the second phase and the act of contraction. The nature of this relation is matter for further investigation.

Linnean Society, June 20.—Prof. Allman, F.R.S., president, in the chair.—Mr. W. Catell was elected a Fellow of the Society.—Dr. J. Gwyn Jeffreys exhibited and made remarks on specimens of a new species of *Virgularia*, dredged by himself and the Rev. A. M. Norman in the Osterfjord, Norway, and which Dr. Danielssen will further describe.—Some gourds, probably the fruits of *Lagenaria vulgaris*, from Pekin, were shown by Mr. J. R. Jackson, of Kew. These, which were quite ornamental in form, had had their figure given them while in the living state by their being inserted into moulds, thus growing to the pattern desired.—A notice of some shells dredged by Capt. St. John, R.N., in the Korean Strait, was read by Dr. J. Gwyn Jeffreys. Of fourteen species enumerated six are now, for the first time, found living in the North Pacific as well as the Atlantic. *Nucinella ovalis* and *Kellia pumila*, supposed extinct, are thus shown recently living in the Korean region. Six other species are already known as inhabiting both oceans. No less than nine of the fourteen species are Coralline Crag fossils. The author finds this collection supporting his formerly expressed view, that mollusca common to the North Atlantic and North Pacific oceans may have originated in high northern latitudes, and have found their way to Japan on the one side and Europe on the other by means of the bifurcation of the great Arctic current.—Chas. B. Clarke read a paper on two kinds of dimorphism in the Rubiaceæ. The group in question is well known to be largely dimorphic, the variations chiefly consisting in the length of the style and stamens. The author now records dimorphism as follows:—1. Where the point of insertion of the stamens is altered, being situate in one form high above the middle of the corolla tube, and in another form at the base of the corolla tube —that is, subepigynous instead of epicorolline. 2. Where there are two kinds of fruit, viz. (*a*) a large fruit corresponding to a sessile flower, &c., and (*b*) a small fruit corresponding to a peduncled flower.—The Secretary read, for Capt. W. P. Armit, some notes on the presence of *Tachyglossus* (= Echidna) and *Ornithorhynchus* in North and North-East Queensland. It is shown that the Echidna occurs at Bellenden Plains, 18° S. lat., which habitat appears to be the most northern limit yet recorded in the Australian continent. The Ornithorhynchus is also met with 150 miles west of Georgetown and on the Leichardt River, about 18° S. lat.—Some remarks on the Echidna skull accompanying the above paper were made by Dr. J. Murie. Its comparison showed that, in all particulars, it agreed with that of the common *E. hystix*, and that supposed to be specifically distinct, to wit, the *E. setosa*. The New Guinea Echidna (*Acanthoglossus Bruijnii*) presents marked characteristic differences from both.—Prof. Oliver communicated a paper by Mr. N. E. Brown on the stapeliæ of Thunberg's herbarium and descriptions of new genera. Of eleven species of stapelia of Thunberg's determination, five only properly belong to the genus as now understood, and six belong to five different genera, two of which (*Trichocaulon* and *Diplocyatha*) are now characterised for the first time. *Sarcocodon speciosum* from the Somali land, and *Huerniopsis decipiens* from South Africa, are curious plants, the genera and species receiving a formal description.—The abstract of a paper on the shell of the bryzoa, by Mr. Arthur W. Waters, was taken as read.—The main points of observations on the white whale (*Beluga leucas*) exhibited at the Westminster Aquarium, were given orally by Dr. J. Murie. These notes chiefly related to the times and manner of breathing, certain outward peculiarities, visual organs and movements of body and tail in progression round the tank, along with other physiological topics. Respiration in and out of the water is not identical as to times and manner. A fungus (*Saprolegnia ferax*, Smith), that lately known as the "salmon disease," grew in abundance on the body of the whale, and no doubt acted prejudicially to the animal's health.

Mathematical Society, June 13.—Prof. H. J. S. Smith, F.R.S., vice-president, in the chair.—Mr. T. R. Terry was admitted into the Society, and Mr. J. D. H. Dickson was proposed for election.—Dr. Hirst, F.R.S., communicated a paper by M. Halphen, on the characteristics of systems of conics.—Mr. J. J. Walker read a paper on a method in the analysis of plane curves. This last paper was the development of a method of treating the intersections of a transversal with a plane curve which occurred to the author some years since; it contained, *inter alia*, a discussion, by the use of the method, of the problem of the inflexion-tangential curve for the quartic, with the determination of the co-ordinates of the tangential point in terms of the co-ordinates of the corresponding point of inflexion.—Mr. Tucker (hon. sec.) communicated the following papers:—On the calculus of equivalent statements, II., Mr. Hugh McColl; On the flexure of spaces, Mr. C. J. Monro; On the decomposition of certain numbers into sums of two square integers by continued fractions, Mr. S. Roberts, F.R.S.; On a new method of finding differential insolvents of algebraical equations, Mr. R. Rawson. —Questions were asked by Prof. Cayley, F.R.S. ("Has a solution been given of the statement that in colouring a map of a country, divided into counties, only four distinct colours are required, so that no two adjacent counties should be painted in the same colour?"); by Mr. Merrifield, F.R.S., on the uniform distribution of points in space; by Mr. Tucker, in connection with the announcement made in NATURE (vol. xvii. p. 104) of a second exception to Fermat's statement that all numbers of the form $2^m + 1$ are primes. The two exceptions now known are for $m = 5, 12$, in which cases $5 . 2^7 + 1$, $7 . 2^{14} + 1$ are factors respectively. Mr. Tucker suggested that $9 . 2^{21} + 1$, $11 . 2^{28} + 1$, &c., might be factors when $m = 19, 26$, &c.

Physical Society, June 8.—Prof. W. G. Adams, president, in the chair.—The following candidate was elected a Member of the Society:—Mr. R. H. Solly.—The Secretary read a paper by Prof. Hughes on the physical action of the microphone.—Sir John Conroy, Bart., M.A., read a paper on the light reflected by potassium permanganate. After referring to the results obtained by Haidinger and Stokes, and more recently by Wiedemann, he proceeded to describe his own experiments, which have been made by means of a very complete Babinet's goniometer provided with a vertical as well as a horizontal stage, so that the reflecting surface could be placed directly over the axis of the instrument. Sunlight, unpolarised or polarised in any plane by a Nicol, was used, and the moving arm of the instrument carried a direct-vision spectroscope with a "bright-spot" micrometer and a reflecting prism for bringing a second spectrum into the field. The colour of a surface, obtained by rubbing the crushed permanganate into a surface of ground glass with an agate burnisher, was found to vary with the nature of the light and its angle of incidence, and it further varied as the surface was immersed in benzene, bisulphide, or tetrachloride of carbon. With light polarised perpendicular to the plane of incidence, the dark bands in the reflected spectrum are far more distinct than when unpolarised or polarised perpendicularly to that plane. In the first of these three cases four bands are observed at angles less than 40°, and the blue end of the spectrum is very weak; as the angle of incidence increases the intensity of the blue rays diminishes: the dark bands gradually shift towards the blue end of the spectrum, and at about 60° a new band appears near D. With a still greater angle more of the blue rays are reflected and the bands fade away, those in the more refrangible part disappearing first. This displacement amounts approximately to 0·006 tenth-metre.—Prof. S. P. Thompson exhibited and described a cheap and efficient form of optical bench. Two straight oak bars, about two metres in length, are clamped together, as in a lathe-bed, and a number of slides carrying various appliances slide easily without shake, and can be fixed in any position by wedges. The several frames carrying the diffraction grating or edges, the eye-piece (with an engraved glass micrometer), &c., are so made, in wood, as to be capable of adjustment in any plane; and the instrument can also be employed for making photometric or other measurements. The mean of two determinations for the wave-length of certain red light gave 0·000629 as compared with Fresnel's figure, 0·000640, while the total cost did not exceed 3*l*.—The Secretary then read a paper by Prof. Ayrton, of the Imperial College of Tokio, Japan, on the electrical properties of beeswax and lead chloride. The

index of refraction of the former substance increases in passing from the liquid to the solid state, and it therefore seems important, in connection with the electro-magnetic theory of light, to carefully measure the specific inductive capacity of a condenser made of wax, as it is cooled through its solidifying point. The rise in capacity, as the temperature falls from 80° C. to 60° C., is very striking, and the entire change was found to be in exact agreement with the changes known to occur in the index of refraction for light. An elaborate series of experiments was made, which sufficed to show that the results obtained were not due to any change in the distance apart of the plates (of copper) between which the wax was placed, caused by any shrinkage of this wax on solidifying. In consequence of a remark of M. Buff that lead chloride behaves as a metal, Prof. Ayrton has studied it as a dielectric, and he found a diminution of resistance by electrification; but as this result was not confirmed on subsequent experiment, the question was more fully investigated, when he found that, with an electromotive force under 1·75 volts, there is an increase in resistance, and above that amount there is a regular or irregular diminution. This limiting force is about that required to decompose water, and he concludes that the results obtained must be due to the damp contained in the lead chloride.

Entomological Society, June 5.—H. W. Bates, F.L.S., F.Z.S., president, in the chair.—Mr. J. A. Finzi exhibited a remarkable hermaphrodite specimen of *Anthocaris cardamines*.—Mr. Rutherford exhibited a series of large cocoons from Mount Camaroons, formed by the larvæ of a species of Bombyx allied to *Anapha panda*, Bdv. These cocoons varied in diameter from four to seven inches, and each one contained from 130 to 150 smaller cocoons, all of which were tenanted by a larva or chrysalis in various stages of development. It would appear that *Anapha panda*, like some other species of *Bombycidæ* is social, and that the larvæ unite to form an aggregate cocoon of sufficient strength to withstand the attack of enemies and probably extreme changes of temperature.—Mr. Rutherford also exhibited a specimen of a *Papilio* as a case of so-called "hermaphroditism" with asymmetrical markings on the wings which approached respectively *Papilio cynorta* and *Papilio Boisduvalianus*, thus creating an impression that those two forms were but the sexes of one species. These specimens were from the collection of Mr. F. J. Horniman.—Mr. Meldola exhibited photographs of two species of tropical orthoptera sent to Mr. Darwin by Dr. Zacharias as an illustration of protective resemblance in the very perfect leaf-like appearance of the fore-wings; and some small beetles of the genus *Spermophague* and their cocoons, which had been found in a packet of seeds of *Cassio neglecta*, sent from Brazil by Dr. Fritz Müller to Mr. Darwin. The full-grown larvæ had emerged from the seeds, leaving the latter in a damaged condition, and had spun the small cocoons from which the beetles had issued, the insects having reached this country alive. Mr. Meldola also exhibited the proboscis of a sphinx moth caught by the narrow tube-like nectary of a pale yellow *Hedychium*, which had likewise been received from Dr. Fritz Müller, who states that sphinges are frequently found caught in ths manner.—Sir Sydney Saunders communicated notes by Mi. M. Lichtenstein, on new ideas as to the life-cycle of aphidians, giving the results of considerable breeding experiments.—The Secretary read a paper from Dr. Fritz Müller entitled "Notes on Brazilian Entomology," in which the author gave the results of his observations on the odours emitted by butterflies and moths, as well as facts bearing on various other subjects more or less connected with the theory of evolution. In reference to this paper the wings of *Antirrhœa archœa* from Brazil, and of *Mycalesis drusia* from the Nicobars were exhibited, in illustration of the author's theory of "scent-fans."—The following papers were also communicated: "On some longicorn Coleoptera from the Hawaiian Islands," by Dr. Sharp. "On the Larvæ of the Tenthredinidæ, with Special Reference to Protective Resemblance," by Mr. Peter Cameron; and "On *Macropsebium coterelli*, and other New Species of Coleoptera from Lake Nyassa," by Mr. H. W. Bates. The author exhibited the remarkable longicorn beetle above designated, which possessed some prominent characters of the Prionidæ.

Royal Microscopical Society, June 5, 1878.—H. J. Slack, president, in the chair.—Major O'Hara and Dr. J. Edmunds were elected Fellows of the Society.—A paper by Prof. Keith, on the results of a computation relating to Tolles' ⅛-objective, was read by the Secretary.—Prof. Stokes read a paper on the question of a theoretical limit to the apertures of microscopical objectives, in which he showed that, theoretically, a pencil of rays from a radiant in glass (or under equivalent conditions) of 180° could be refracted by a single refraction at a spherical surface, so as to present to the second lens a pencil of about 81° free from spherical aberration; and, while not asserting the possibility of utilising the whole of the pencil of 180° in glass, he thought a very large part of it might be available in a practical construction—a far larger part than can be used with dry lenses. The subject was further discussed by Messrs. Ingpen, Stephenson, and Mayall.—The other papers were on the measurement of the diameter of the flagella of *Bacterium termo*, by the Rev. W. H. Dallinger; on the framework of the mastax of *Melicerta ringens*, by Mr. F. A. Bedwell; a translation by Mr. Kitton of a paper by M. Petit on some new genera and species of diatoms; and a note by Mr. J. H. Stephenson on the effect produced on *Pleurosigma angulatum* by stopping out the central dioptric pencil. Mr. Stephenson exhibited, after the meeting, *Pleurosigma angulatum*, with his new oil-immersion lens, under the conditions explained in his paper; and Mr. Mayall demonstrated the aperture of Tolles' ⅛-objective, by Abbe's apertometer, to be largely in excess of the maximum possible for dry lenses. Some extremely good slides of the mastax of *Melicerta* and *Conochilus*, mounted by Lord S. G. Osborne, which had been sent by Mr. Bedwell, were also exhibited.

Meteorological Society, June 19.—Mr. C. Greaves, F.G.S., president, in the chair.—J. C. Philips and W. S. Rawson were elected Fellows.—The following papers were then read:—The climate of Lundy Island, by A. J. H. Crespi, B.A., F.M.S. Lundy Island, from its geographical position, might be expected to have a mild, damp climate, with cool summers and warm winters, and a small diurnal range of temperature, and so, no doubt, it has, although certain local circumstances in addition to its peculiar configuration make the climate remarkably inclement, windy, and unpleasant. The island runs nearly due north and south, having an extreme length of four miles and a breadth of from 200 yards to 1,600 or 1,800; there is a nearly flat table-land or "top" running due north and south, having an altitude of 450 feet; shelter there is none, every current of wind sweeps the whole table-land. From the edge of this table-land the ground slopes away to the sea; sometimes the descent of the side-land is extremely abrupt, at other spots more gradual, while the side-lands are deeply cut by caves, precipices, small bays, and glens. All around the island the water is deep a few hundred yards off, while the currents are formidable, and tremendous seas break upon the rocks almost every day in the year. The *one* drawback of the place is the wind, so furious and continuous are the blasts first from one quarter, then from another, for days and even weeks. When gales occur, as they generally do at short intervals, the force of the wind becomes incredible: walls are torn down, gates and doors wrenched out of their fastenings, and the few buildings which can be blown down are more or less injured. Fogs are remarkable for their frequency and density, and are nearly always drenching. The rainfall is nearly 50 inches per annum. February and March are said to be the coldest months and August the hottest; the mean temperature of the year is about 50° or 51°.—On the auroral or magnetic cirrus, by the Rev. S. Barber, F.M.S.—Contributions to the meteorology of Natal, by Dr. R. J. Mann, F.R.A.S. This paper is a discussion of the observations taken at Maritzburg (2095 feet above sea-level) during the six years 1860–65; from it we learn that the summer of Natal is a season of copious rain and the winter a season of relative dryness; also that the former is a time of abundant and frequent cloud, and the latter a time of preponderant sunshine. The summer is consequently cooler in a material degree than it would otherwise be, on account of the frequent prevalence of cloud and the abundance of the rainfall; and the winter has its temperature materially raised from the constant occurrence of clear skies and bright sunshine. The mean annual rainfall was 31·13 inches, of which amount nearly 28 inches came down during the six summer months (October to March), and scarcely more than 2 inches during the four midwinter months (May to August). Thunderstorms are of frequent occurrence, the average exceeding seven per month from October to March. The thermometer rarely rises above 85° in the shade even in the summer months, unless a hot wind is blowing; it then mounts to somewhere between 85° and 97° according to the strength of the sirocco. The degree of humidity indicated

by the dry and wet bulb thermometers when a hot wind is blowing varies from 25° to 52° of moisture. The highest temperature recorded during the six years was 97°·6, the lowest 29°, and the mean 63°·3.—Note on the mean relative humidity at the Royal Observatory, Greenwich, by W. Ellis, F.R.A.S. In this paper the author gives the mean relative humidity in each month of the year at 9 A.M. and 9 P.M., and the mean of the twenty-four hourly values, derived from the photographic records of the dry and wet bulb thermometers for the twenty years 1849-1868. The 9 A.M. value is smaller than the mean in summer and larger in winter; and the 9 P.M. value is larger than the mean throughout the year, but most in summer. The mean monthly values change little from April to August, and from October to February; and there is a great decrease between February and April, and a corresponding great increase between August and October. The mean for the year is 80·7.—On a method of sometimes determining the amount of the diurnal variation of the barometer on any particular day, by the Hon. R. Abercromby, F.M.S.—On the relative duration of sunshine at the Royal Observatory, Greenwich, and at the Kew Observatory, during the year 1877, by G. M. Whipple, B.Sc., F.R.A.S. The author having instituted a comparison of the amount of sunshine recorded at these two observatories, finds that the totals show that for the whole year the excess in the number of hours the sun shone at Kew over the number at Greenwich, amounted to 171. This difference is no doubt due to the direction of the wind, for Greenwich lying to the south-east of the chief part of London, and having also large manufacturing establishments on its northern side, is greatly shaded by cloud, probably in a great measure due to smoke, when the wind blows from W., N.W., or N., while at Kew, which is situated to the west of London, and is remote from factories and shipping, enjoys a larger percentage of sunshine with these winds. With winds from the N.E., S., and S.W., Kew has but slight advantage over Greenwich. With E. and S.W. winds the London smoke is driven over Kew, and its presence in reducing the transparency of the air is evident in the diminished amount of sun recorded, the quantities being only 81 and 65 per cent. of those registered at Greenwich.—Account of the atmospheric disturbance which took place in lat. 21° N., and long. 25° W., on January 27-28, 1877, by J. H. Cardew.—Notes on some remarkable cloud formations accompanying sudden and frequent changes of temperature and wind, by Capt. W. Watson, F.M.S.

VIENNA

Imperial Academy of Sciences, February 28.—The following, among other papers, were read:—On some sensations in the region of visual nerves, by M. Brücke.—On the galvanic polarisation of platinum in water, by M. Exner.

PARIS

Academy of Sciences, July 1.—M. Fizeau in the chair.—The following among other papers were read:—On sulphuric saponification, by M. Fremy. He expresses his satisfaction because this process, *without distillation* (which discoloured the fatty acids), is now become an industrial operation, as the Exhibition proves.—On a system of telephone without electromagnetic organs, based on the principle of the microphone, by M. du Moncel. A reference to recent results by Blyth, Hughes, &c., in this direction. He thinks some of the sounds heard in telephones connected with telegraph lines may arise from friction of the lines on their supports.—On diphtheria in the East and especially in Persia, by M. Tholozan. There is no record or tradition of croup, scarlatina, or diphtheritic or gangrenous angina in Persia previous to 1869. In that year and the next a small epidemic of scarlatina appeared. In 1874 an epidemic of diphtheria broke out in the south of Persia and spread towards the north and west. Particulars are given.—M. Friedel was elected member in the section of chemistry in room of the late M. Regnault.—Thermal researches on the chromates, by M. Morges. The electrolytic decomposition of the chromates is not comparable to that of the alkaline sulphates. The heat confined does not exceed 12,500 calories. The chromates are rather comparable (thermally) to the carbonates.—*Trombe* of May 15, 1878, in the department of Vienne, by M. De Touchimbert. This appears to have been very violent, uprooting strong trees, damaging houses, lifting railway carriages, and throwing persons down. Its course (about forty kiloms.) was from S.S.W. to N.N.E. and E. Its width was 1,000 to 1,200 m.; velocity about 44 m. per second; pressure about 220 kilog. per square metre.—On the deformations of the disc of Mercury during its transit, by M. Lamez. Calculation shows that an advance of 8 sec. on the theoretical instant of contact may have been produced by the ellipticity; and an advance was observed.—On a single liquid pile depolarised by the action of atmospheric air, by M. Pulvermacher. The exciting liquid, (dilute sulphuric acid, caustic potash, or sal ammoniac) is placed in a porous cylindrical vessel. The positive metal is a rod of amalgamated zinc placed in this vessel, and the negative consists of long bell-springs of fine wire (silver or platinum) coiled round the cylinder, their coils sufficiently apart to avoid capillary action. The wire is thus in contact at a great many points with the liquid which transudes the porous vessel, and the external air has a continual oxidising action on these numerous small surfaces of tangence, thus effecting depolarisation.—On a new mode of formation of glycolate of ethyl, by MM. Norton and Tchermak. This is by action of glycolide on ethylic alcohol.—On the action of chlor-hydrates of amines on glycerine, by M. Persoz. On heating, *e.g.*, glycerine with chlorhydrate of aniline, one easily obtains phenylised derivatives of glyceramine along with secondary products.—On anærobiosis of micro-organisms, by M. Gunning. With the aid of ferrocyanide of ferrosum, which he found an extremely sensitive reagent for oxygen, he had shown that the apparatus and media commonly used for culture of micro-organisms cannot be freed from oxygen by the methods recommended for this purpose. In a memoir to the Amsterdam Academy, he gives arguments for attributing the cessation of putrefaction solely to the death of the bacteria, caused by absence of free oxygen. M. Pasteur considers that putrefaction is sometimes stopped because the small organisms have passed into the state of germs.—On the "piedra," a new species of parasitic affection of hair, by M. Desenne. This consists of hard nodosities (visible to the naked eye) at regular intervals on the hair. It is met with in the province of La Cauca, Columbia. It is cured by greasing the head well, and is not contagious.—On the explanation of the effects of irrigations practised in the south of France, by M. Barral. These are important, not only on account of the matters brought by the water, and the satisfaction of the need of moisture, but on account of the reactions they favour in the layer of earth necessarily moistened, aërated, and put in contact with mineral or organic compounds.—Letter from Prof. Du Bois Reymond presenting two new volumes of his researches on the physics of the muscles and the nerves. They contain memoirs published since 1855.—A memoir by Prof. Villari was presented, on emissive power and the different kinds of heat which some bodies emit at 100°.

THURSDAY, JULY 18, 1878

THEODORE SCHWANN

On Sunday, June 23 last, a very interesting ceremony took place at the University of Liége, in Belgium, in honour of Schwann, the famous author (with his fellow-worker Schleiden) of the so-called "cell theory." So rapid has been of late years the progress in our knowledge of the minute structure of animals and plants that Schwann's name seems already to belong to the distant past, and not a few biologists appear to have been, up to the last few months, under the impression that the distinguished author of the "Microscopical Investigations into the Identity in Structure and Growth of Animals and Plants" had long ago been laid in the grave. We rejoice to say that, on the contrary, he is alive and to outward appearance hale and vigorous, though he has had some warnings which have led his *confrères* at Liége to celebrate this year, as a sort of premature jubilee, the fortieth anniversary of his professoriate rather than wait till the full tale of fifty years had been told.

Theodore Schwann was born at Neuss, near Düsseldorf, on December 7, 1810. In 1829 he entered the University of Bonn, first as a student of philosophy, but afterwards as one of medicine. The illustrious Johannes Müller was at that time a privat-docent at Bonn, and Schwann, like so many other of the distinguished biologists of the present day, owes much of his success in life to the vivifying influence of that distinguished teacher. From Bonn Schwann migrated to Würzburg and thence to Berlin, whither Müller had been called to fill the chair left vacant by the death of Rudolphi. Here Schwann, working with the support and under the guidance of Müller, carried out several physiological investigations, the most notable of which were those on the respiration of the chick in the egg, on artificial digestion, on the structure of muscular fibre and of elastic tissue, on the contractility of the arteries, on the mechanics of muscular contractions, and on spontaneous generation. All these researches made their mark and added to our knowledge. Many readers will doubtless remember the ancient myograph employed by Schwann, which was exhibited at the collection at South Kensington two years ago. Besides this, Schwann appears to have largely assisted Müller in the experiments and observations necessary for the construction of the well-known text-book of physiology. Lastly, in 1838, he began to publish, in Froriep's "Notizen," the views which had arisen in his mind concerning the cellular structure of organic beings, and in 1839 laid them before the world in a complete form under the title of "Microscopische Untersuchungen über Die Uebereinstimmung in der Structur und dem Wachsthum der Thiere und Pflanzen." It is unnecessary here to point out the immense effect which the "cellular theory" has had on the progress of all branches of biology. It has made itself felt throughout the whole domain of physiology and pathology, and in a very remarkable manner prepared the way for the more recent doctrines of evolution. During the forty years which have elapsed since it was first enunciated, it has undergone considerable changes: it has been hammered by the blows of repeated labours into a form more durable than that in which it first appeared; but it still remains as the cellular theory. And this at least may be said, that Schwann himself, in expounding his views, kept remarkably clear of the many vagaries in which his immediate followers indulged, and which for a while threatened to make the cellular theory a reproach rather than an honour.

While engaged in these labours Schwann held at Berlin the post of assistant to the Museum, giving as well private courses on histology, and he was on the point of being made Professor Extraordinary when he received an invitation to the chair of General and Descriptive Anatomy at the University of Louvain. This he accepted, and entered upon his duties at the close of the year 1838. In 1848 he was made professor of the same subject in the University of Liége, and here he has remained ever since, exchanging in 1858 his chair for one of Physiology.

During his stay in Liége his life has not been an idle one, but the fame of his earlier labour somewhat throws his later work into the shade, and he is now enjoying the repose which is not only fitting to his age, but which has in every way been most thoroughly earned. The enthusiastic reception which he received at his jubilee from the students of the university showed very clearly how dearly he is loved and how highly he is honoured by those who have still the privilege of being taught by him.

The ceremony of the 23rd began at one P.M., when the Rector of the University delivered in the Aula an oration laudatory of Schwann, at the close of which he unveiled a very successful bust. A large audience was present, among them a considerable number of ladies and students. Prof. Edouard van Beneden then gave an admirable account of the scientific labours which were that day being honoured; after which a student, in a speech which was repeatedly applauded with much enthusiasm, described how greatly Schwann was admired and beloved by his pupils. Then followed the presentation of addresses from various universities and learned bodies. It would be impossible to enumerate these, for they came from all parts of the world, those from Berlin, Vienna, and Heidelberg being especially elaborate; a goodly number arrived from Great Britain. The time of year chosen for the ceremony being unfortunately in the middle of the academical summer session very few representatives were able to attend in person. There were present, however, as bearers of addresses which they delivered with suitable speeches, Prof. Waldeyer, from Strassburg, Prof. Gussenbauer, from Prague, Mr. F. M. Balfour from Cambridge, England (charged personally, in the unavoidable absence of Dr. M. Foster, with congratulations from the Royal Society, from Trinity College, Cambridge, from the Physiological Society, and from the professors and lecturers of the University of Cambridge), and Prof. Pilar, from Agram.

The ceremony was concluded by a genial speech from Schwann, in which he gracefully acknowledged the compliments which he had received. A banquet followed at which the toasts of "The King," "Schwann," "The Strangers," &c., were given, the latter being responded

to by the distinguished biologists present. In the evening a pleasant excursion was made into the surrounding country.

A splendid album had been manufactured at Vienna for presentation to Schwann, containing the photographs of almost all living biologists. Unfortunately it arrived too late to be formally presented at the ceremony. The expense of the bust was defrayed by subscriptions in Belgium, though a few strangers (among them Mr. Darwin) had an opportunity of contributing.

The whole ceremony was extremely interesting and successful, and we trust the hero of it may still live many years in which he may have the pleasure of looking back upon his jubilee, and of feeling that his labours have been appreciated by his age.

A TRANSLATION INTO GERMAN

Grundzüge der Anatomie der wirbellosen Thiere. Von Thomas H. Huxley, LL.D., F.R.S. Autorisirte deutsche Ausgabe, von Dr. J. W. Spengel. (Leipzig, 1878.)

SO far as we know, amongst the many German text-books on anatomy and physiology there is not a single one which is at all carried out on the plan of Huxley's Manual of the Anatomy of Invertebrated Animals. The great merits of the work appear to us to be, firstly, that it combines up to a certain point the features of a treatise on comparative anatomy and on zoology, and secondly, that by the introduction of a description of a type selected from each group, the learner is both greatly assisted in the practical study of animal morphology and also supplied with certain definite centres round which to group the multitudinous facts which he learns in the course of his reading. We flattered ourselves that by the translation of this work into German we should to some extent repay our Teutonic neighbours for the many text-books we have received from them. Our belief that this work was likely to be appreciated in Germany has, however, been very rudely dispelled. We learn from the distinguished naturalist who has undertaken the translation, and whose large experience (we believe his name has been before the public for so long a period as two or three years) gives corresponding weight to his opinion that the work is neither a handbook nor a text-book. He informs us in his preface that "he has decided not to give the work the title of handbook, in order to avoid labelling it with a title which it does not deserve" (um dem Buche nicht einen Anspruch unterzuschieben, den es nicht erheben will). "It is," he goes on to say, "no handbook in the sense customary with us, and indeed can be regarded as a text-book (Lehrbuch) only in the sense that it is intended for learners." In fact, on the unimpeachable authority of Dr. Spengel, Prof. Huxley's Manual of Invertebrata, which has already become the acknowledged handbook in England, is quite unworthy of such a position. In this country we have been accustomed in our simplemindedness to think that Prof. Huxley possesses a singular talent for exposition, while his reputation amongst us as an anatomist is based on our belief that his knowledge of anatomical facts is as wide and extensive and as well kept up as his critical judgment is acute, and his treatment of morphological problems broad and original. We have for some time past been under the idea that Prof. Huxley has had a good deal to do with the progress of animal morphology during the last twenty or thirty years. But we live to learn, and we feel very grateful that a man of Dr. Spengel's standing should show us how imperfect and unequal (lückenhaft und ungleichmässig) is Prof. Huxley's treatment of the subject to which he has devoted his life.

So impressed apparently was Dr. Spengel with the faults of the work which he had obtained permission to translate, that, as he explains in his preface, he asked Prof. Huxley to rewrite the work, in order that the German translation might appear more worthy of the translator's reputation. Singularly enough, Prof. Huxley, with an indifference to the appearance of any translation at all, which must have seemed strange to the translator, declined this modest request. And we gather that he invited Dr. Spengel to modify the earlier chapters (written long ago) in accordance with the views based on later researches, and expounded in the later chapters. The labour involved in such a change was apparently, not congenial to Dr. Spengel, whose energies seem more at home in writing prefatory remarks.

It is with the illustrations, however, even more than with the text of the original, that Dr. Spengel is offended. He expresses the view that the choice of these must have been made on grounds of economy. The larger number are, he says, "derived from the older works of Huxley, and the remainder from the well-known handbook of Owen (aus dem bekannten Owen'schen Handbuche), and other sources." We find some difficulty in understanding the translator's preface at this point. We presume that by "the handbook of Owen" he refers to Owen's "Lectures on the Comparative Anatomy of Invertebrates." We should very much like to know what illustrations are referred to, since, as far as the editions of Owen's lectures obtainable in this country are concerned, none of the figures of that work have been borrowed for Prof. Huxley's Invertebrata.

The translator informs us that he has thought fit to set aside many of Huxley's figures and to add new ones from well-known sources. He has, moreover, had a considerable number of the figures redone. In some of these cases we admit that some improvement has been effected by the alteration of the figures. The two figures copied from Ludwig to illustrate the anatomy of Comatula are excellent, and the substitution of Butschli's figures of Pilidium, for the somewhat erroneous ones of Leuckart and Pagenstecker, effects a decided improvement. In other instances the translator, in his zeal to make the figures clear, appears to have forgotten that it is also desirable to make them true to nature. Thus Fig. 77 does not appear to us to be so true a representation of the appendages of Astacus as the original figure of Huxley, which the translator has set aside; and in Fig. 80 the heart and vessels of Astacus are very far from being as true to nature as they should be. We think also the translator, in adding new figures, should be careful about the references. In the first two figures he has substituted for those of Huxley—Fig. 9 and 35-37—we find wrong references. On the whole the improvement is not so great as might have been expected. Every one is aware that for years past the illustrations of German scientific works have been far superior to those of English ones.

Such a superiority is less obvious than usual in Dr. Spengel's production. Either Dr. Spengel was generously unwilling that the difference should be too striking, or Prof. Huxley's malign influence has extended to the German engraver and printer.

Considering the view which the translator appears to take of Huxley's "Manual," we were rather surprised that he should jeopardise his great reputation by undertaking the translation of so inferior a work. Our astonishment may easily be imagined on finding on the back of the work that the *authorship is attributed to Spengel as well as to Huxley*. The outside of the book, as seen on the book-shelf, reads thus:—

HUXLEY-SPENGEL
ANATOMIE
DER
WIRBELLOSEN THIERE.

The only explanation which occurs to us of this unusual blending of the names of author and translator is that Dr. Spengel felt that the prominence of his name was necessary in order to ensure, for the production of so feeble an anatomist and so imperfect a writer as Prof. Huxley, a circulation large enough to bring about the pecuniary result for which the translation was made. Men have been known to make translations for the sake of a sort of parasitic, or rather "commensal" reputation; but in this case, since Dr. Spengel seems to be the superior of Prof. Huxley, some other object must have been foremost in view.

Seriously speaking, we hardly think Dr. Spengel can have fully realised the effect which such a preface would have upon the ordinary reader. Had he done so his behaviour towards Prof. Huxley would have been of a kind for which we should hesitate to use adjectives adequately descriptive. F. M. B.

MERRIMAN'S "METHOD OF LEAST SQUARES"

Elements of the Method of Least Squares. By Mansfield Merriman, Ph.D., Instructor in Civil Engineering in the Sheffield Scientific School of Yale College. (London: Macmillan.)

THE method of least squares has an extensive literature of its own. Our author, in a sketch appended to his work, gives the titles of forty-seven of the most important memoirs and books which treat of this subject and of the law of errors of observation. He further "takes the wind out of the sails" of his reviewers by saying: "It would be easy to greatly extend the limits of this list. The titles have, in fact, been selected from a list of about four hundred, which I hope some time to publish, accompanied by historical and critical notes." Though this is an unkind cut, inasmuch as a reviewer will hardly care to bring forward any references of his own, we yet trust Dr. Merriman will be sufficiently encouraged to bring out this promised contribution to the history of a particular branch of mathematics. The writer's objects are "to present the fundamental principles and processes of the method in so plain a manner and to illustrate their application by such simple and practical examples as to render it accessible to civil engineers who have not had the benefit of extended mathematical training; and secondly, to give an elementary exposition of the theory which should be adapted to the needs of a large and constantly-increasing class of students." Hence the book is both a practical and a theoretical one. The first part is concerned with the adjustment and comparison of engineering observations in which, after giving an introduction on the principles of probability and the method of least squares, he treats of direct observations upon a single quantity and independent observations upon several quantities, conditioned observations, and the discussions of physical observations.

The second part is devoted to the theory of least squares and probable errors; in this, after a deduction of the fundamental principles, he proceeds to the development of practical methods and formulæ.

In an Appendix he gives Gauss's method of solving normal equations, a list of literature (referred to above), remarks on the theory of least squares, and a few other short notes. A full index is given at the end. There is frequent evidence that the writer has carefully consulted the memoirs he cites in his list, so that while there is nothing of novelty in his treatment that treatment is founded upon the best authorities.

"As I have not written for mathematical experts, they will doubtless find considerable (*sic*) in the book at which to grumble." He points out what may be considered blots in his book. One is that he has adopted Gauss's development of the law of probability of error as the best adapted to an elementary presentation; "If this be objected to as defective, I claim at least the credit of knowing and of pointing out just what and where those defects are."

A consequence, perhaps, of having the work printed in this country is the list of errata. We would suggest in the event of the publication of the historical list, that the dates of reading of the memoirs should be given rather than (or at any rate in addition to) the dates of their publication.

We welcome this work as an evidence of the increasing attention that is being given to mathematics by the author's fellow-countrymen, and hope he will be encouraged by its reception here to follow up its publication with a promised work containing extended applications of the method to higher geodetic surveying and the other problems to which it can be and has been applied.

OUR BOOK SHELF

Holmes' Botanical Note-Book, or Practical Guide to a Knowledge of Botany. By E. M. Holmes, F.L.S., Curator of the Museum of the Pharmaceutical Society of Great Britain, late Lecturer on Botany at Westminster Hospital. (London: Christy and Co., 1878.)

FROM the author's experience at the Pharmaceutical Society, together with that gained during the time he held the lectureship at Westminster Hospital, he is likely to know pretty well the requirements of the students at the pharmaceutical and medical schools. It is not always, however, that a teacher, well acquainted though he may be with what is wanted by the students, is capable of providing the best material to supply those wants. In this note-book we think Mr. Holmes has succeeded in smoothing the path of the botanical course, often so uninteresting and consequently amounting to drudgery to many a student. The plan adopted of

arranging one part so as to work in with another, or rather to lead up to it, is a good one. The aim has been, not to simplify terms, which has often been attempted with varying success, but to reduce as far as possible the difficulty always attending a clear understanding of the meaning of the terms, and indeed to simplify the whole system of teaching. "To this end," the author says in his preface, "two charts of the natural orders are given, in which the diagnostic characters are reduced to a minimum, those which are most easily observed having been chosen as far as possible in preference to the more minute, while all the exceptions have been indicated in an appendix. It is hoped that in this way, the student being familiarised with all the exceptions likely to be met with in this country, some of the difficulties attending a practical study of botany will be removed." The three diagrams of scarlet geranium, daisy and dandelion, and narcissus will be found very useful, as each part of the plant is very distinctly named on the plate itself and is furthermore minutely described in two and a half pages of letterpress. The glossary with the Latin terms accented will be a great help to a young beginner and the interleaving of this part is a good point. Altogether we think the book is very satisfactory. We should, however, have preferred to see the sixty schedules placed at the end of the book rather than in the middle. Placed where they are, one is led to suppose there is no further matter beyond them, which is not the case, the charts and a very useful "Floral Calendar" being placed at the end.

Grundzüge der Electricitätslehre. Zehn Vorlesungen von Dr. W. v. Beetz. (Stuttgart: Meyer and Zeller.)

Dr. von Beetz has published a series of lectures delivered to the members of the medical association in Munich. These lectures do not pretend to contain an exhaustive treatment of the subject. They are meant to illustrate the fundamental principles of the science by a series of well-devised experiments, and they amply fulfil the object for which they have been written. The little book contains much matter in a small space, and is throughout clear and to the point. It will be useful to a wide class of readers especially as an introduction to more detailed treatises. Objections might be raised against some incidental and more speculative remarks; but these are very few in number, and do not affect the chief aim of the book. A. S.

LETTERS TO THE EDITOR

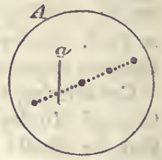
[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Measuring Scales for Pocket Spectroscopes

In using small spectroscopes, such as miniature pocket instruments, to examine coloured flames, and to discover to what particular substances they owe the characters of their radiation, the power of such discrimination which these instruments possess is for many reasons very limited and circumscribed if they are unprovided with some description of dark-field illuminated scale of regular divisions. I have found the following description of measuring scale, when adapted to such small spectroscopes, answer ordinary purposes of recording bright-line positions with them very well, although it was for viewing faint lines in auroral spectra that it was originally devised, for which I have not yet had an opportunity to test its suitability with the same success.

The circular disc A is a piece of copper foil in which a fine slit *a* is punched, and oblique to it a row of twenty holes is punctured, five on the left and fifteen on the right of the slit, the highest and lowest holes of the row being level with its top and bottom points. The actual size of the disc is just half the size of this figure, and to puncture the holes at equal distances apart of about $\frac{1}{80}$th of an inch, either a dividing engine must be used and a needle-point drawn along the sloping face of a straight edge is pressed down with the equal pressure of a weight upon the disc laid on zinc or ivory, to puncture it; or a rack of fifteen or twenty of the finest sewing needles, side by side, may be so fixed in fusible metal as to produce the whole row of punctures by a single pressure. But the first method, even with a roughly made dividing engine for the purpose, I have found the easiest and the most successful plan. The disc takes the place of the jaws of a pocket spectroscope, being dropped into a recess where it is covered by a glass plate and held in its place by a brass ring or perforated cap screwed upon the end of the spectroscope. When viewed through the prisms by sodium light it is seen magnified by the eye-lens, and the punctures form a scale of bright yellow points to the right and left of the yellow sodium line produced by the slit.



With sufficiently large punctures it is probable that the monochromatic yellow-green auroral ray would render the punctured scale visible in the same way that the sodium light does, so as to supply a measuring scale on which other spectral rays of the aurora's light besides the greenish one produced by the slit may be observed and recorded in their actual positions of distance from that leading line. Even the chief green ray of the solar corona in a total eclipse would not improbably illuminate the oblique scale sufficiently to allow the positions of other rays occurring in its spectrum to be recognised and mapped with ease and with considerable accuracy with a pocket spectroscope.

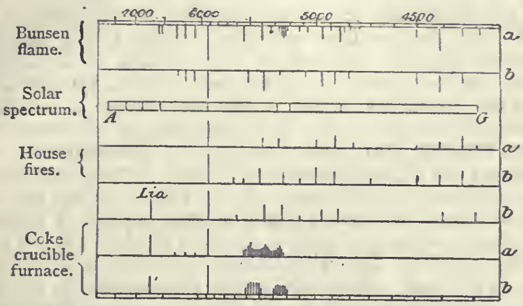
The object of inclining the row of punctures obliquely from a horizontal line is that other coloured images of it besides the principal or brightest one chosen for reference may not mix with and confuse its divisions. There is no means of varying the width of the slit in the arrangement, and I have not succeeded in obtaining microscopic scale photographs on glass sufficiently dense and opaque to replace the metallic punctured scales, and the focus of the eye lens for the yellow sodium points is not exactly the same as for very refrangible blue lines that coincide with them in position in the field of view; but an assortment of discs can be used and may be placed at pleasure in the cell, and the objection of the unequal focus is at least removable by using an achromatic lens. With these drawbacks to its use, however, the punctured scale has one essential advantage over laterally reflected ones, that its relation to the spectrum which it is used to measure always preserves an invariably fixed adjustment.

The presence of sodium light is so easily supplied where it is wanting that there are very few conditions (even if another bright spectral line cannot be chosen) in which the punctured scale is not available. The wave-length curve for each spectroscope is then easily constructed from observations of known elementary metallic lines in flame spectra in which the sodium line is always available for a line of reference. I have obtained this curve for both a punctured scale spectroscope and also for a Browning's miniature spectroscope with a reflected scale, and have examined several commonly occurring flames in furnace and other fires with the result of detecting in them some metallic spectra. Lithium is thus very often found, sometimes almost as bright as the sodium line, in coke furnace fires; and I have frequently observed in ordinary house fires a flame of rich blue colour with a very characteristic spectrum, which I now recognise by measurements as agreeing with that of copper chloride obtained by moistening copper foil with hydrochloric acid in a Bunsen-flame.

The accompanying figure (projected as nearly as the small size of the drawing permits, in tenth-metre wave-lengths) shows the appearance of the natural and artificial spectra, and their close resemblance, showing very clearly that some compound of copper is the cause of the very brilliant blue colour of the natural flame. Its finest exhibition in house-fires (where it quite filled a grate) arose from blazing wood-logs, which were described to me as broken-up ship-timber, in which traces of copper chloride might reasonably be expected to occur, and it is in the wood of fires that its hyacinth-blue flame has usually attracted my attention; but the same spectrum with three neat pairs of

lines, green, blue, and indigo, was noticed also in jets of flame projecting from above the lid of a coke crucible furnace in which copper and brass were being melted (the first of the three furnace spectra in the figure), where the presence of a chloride would not be so readily suspected. The same furnace was revisited, and fired for experiment in different ways, but it only showed the copper-flame spectra drawn in the last two lines of the figure, whose total colour is olive, or tawny green, quite different in aspect from the rich blue of the flame first seen and identified with that occurring in ordinary fires. As refuse brass and copper articles are consigned for melting to these crucibles, it is, however, not improbable that copper chloride may in this instance have been introduced among them.

Attempting to discover the cause of the blue fire-flame by examinations of artificial spectra led me to try that of the blue flame found by Prof. Barrett (NATURE, vol. v. p. 483) to be produced when a burning jet of hydrogen is allowed to play upon



Spectra of the blue flame of copper-chloride, naturally and artificially produced; observed, *a*, with Browning's miniature spectroscope with reflected micrometer scale; *b*, with punctured-scale pocket-spectroscope.

the surface of sulphuric acid, or upon the surface of any object, indeed, which has contracted dust by exposure to the air. It is very abundant, and readily produced everywhere, and not less intensely blue than the copper flame; but no distinct measurements or notable appearances of its spectral bands could be obtained. I could, however, corroborate Prof. Barrett's observations of the extension of the blue colour only on the surfaces touched, and its want of penetration into the body of the flame; and I noticed that metal surfaces rubbed with sulphur which remain cool exhibit it more brightly than wood or other sulphurised surfaces which are quickly heated in the flame. A paste of coke-dust and sulphur wetted with water ceases to tinge the flame (as does also sulphuric acid) when it grows warm, and it fails to colour it when dry. The brightest blue flame was obtained by directing the burning jet upon a mixture of snow with coke dust and sulphur, pounded together in a mortar, the reason apparently being that great attenuation of the sulphur-vapour, and therefore a low temperature of the sulphur, is required to enable the sulphur compound formed to exhibit its characteristic blue-coloured spectrum in the flame.

Zoological Geography—Didus and Didunculus

MY use of the expression "a near congener" seems, from Prof. Newton's letter in your number of July 4, to have diverted attention from the point to which I desired to direct it.

If the bird of the Navigator group had presented such near congenerity to the Dodo as does the other of the ground birds (*Pezophaps*) known from the Mascarine Archipelago, this would have been startling, but as it is the degree of relationship (I avoid the word "congener" which gave rise to Mr. Newton's correction) seems to me to bear out the argument as to former geographical connections which I so long ago advanced.

Both birds belong to the *Columbæ* and to that all but extinct branch of the family to which the term "ground dove" has been applied; and the wingless condition of the Dodo has been by one great living authority accounted for on the hypothesis that by being confined to islands and so secured against enemies, and finding food on the ground, this queer pigeon gradually lost the necessity for, and with this the use of its wings, and thus acquired its bulky form and ground habits. Instead of this, however, I believe that both the *Dididæ* and *Didunculus* are survivors from mezozoic times, of a great family in which the characters that connect these ground birds with the winged *Columbæ* were those common to a large order of wingless birds that, like other orders of mezozoic life, have since perished. From this ancient order of life, or from some yet more ancient stem combining their common characters, the winged *Columbæ* may have been evolved; but of the order itself *Didunculus* has, I believe, survived at the eastern side (longitude 170° W.) of the ancient continent to which I in my first letter alluded, and the Dodo and its kindred at the western (long. 58° E.), in both cases by the protection afforded by insulation.

The application which I sought to make of this to the case of the tortoises was that the presence of those reptiles in the Mascarine and Galapagos archipelagos is due to the same geographical change. The osteological differences between the tortoises of the two regions may, perhaps, be less than those between *Didus* and *Didunculus;* but if so, this, in a lower and cold-blooded grade of vertebrate life, would not weigh much; and my contention is that the tortoises of the Galapagos are insulated there by survival from the eastern extremity of this ancient continent, and those of Aldabra, in the Mascarine region, by survival from the western, instead of from land extending across Africa and the Atlantic to South America, as supposed by Dr. Günther. The fossils of the Himalayan and Mediterranean regions prove that the great tortoises lived on the Europeo-Asiatic continent in miocene and older pliocene times (becoming extinct during the latter), but this does not appear to me to negative the conclusion drawn above.

To prevent misconception, I should, perhaps, add that the land tract from the submergence of which the Mascarine archipelago and the differentiation of the *immediate* kindred of the Dodo originated (as suggested by Prof. Newton in the memoir in the *Phil. Trans.* of 1869, to which he refers), was in my view but a fragment of the more ancient and far more extensive continent which (in 1860) I attempted to show occupied the southern hemisphere in mesozoic times; and that such fragment, again, was but a remnant of a still larger portion of this great southern continent, which, as far back as the triassic period, had become separated from the Australian portion, and, so late as the earlier part of the tertiary, occupied much of the Indian Ocean, where, during the eocene or miocene periods, it formed the cradle of the human race.

SEARLES V. WOOD, JUN.

July 13

P.S.—Dr. Forbes speaks of *Didunculus* being somewhat plentiful still in Upolu.

Smell and Hearing in Insects

IN NATURE (vol. xvii. pp. 45, 62, 82, 102, 162–3), which has just reached me, I see a discussion as to the senses of smelling and hearing in moths, to which I add my mite as an old observer.

I do not see how any one can doubt the first. What but the sense of smell directs nocturnal insects to their food? At this moment I have in my verandah a parrot, which is daily regaled with a portion of a banana. Every evening I see a dozen, or more, of the large *Sphingidæ* and *Noctuæ* trying to effect an entrance into the cage to get at the rotting fruit, *which is generally invisible* from the outside, being behind the flap of wood that serves for a door; the cage is only a rough box. I have always found bananas the best bait to attract the night-flyers, *but only when they began to rot.*

Again, how about "sembling"? Here the odour must be very subtle. A virgin female is instantly detected, while not one "gay Lothario" will visit a captive matron.

It is harder to say whether insects *hear* sounds, or *feel* them, as the same effect would be produced on them by either faculty. I have seen both moths and butterflies turn towards sound, and direct their antennæ to it, moving them to and fro. I have noticed larvæ—as remarked by one of your correspondents—assume certain attitudes on being affected by sound; these attitudes are, I think you will find, generally those assumed for protection or concealment; the creatures are, in fact, alarmed at the unusual—noise? or vibration?—which?

I will adduce one remarkable case in support of the smelling power. Years ago I had (while residing in the North of Ceylon) a lot of living *Achatina panthera* sent to me by the late Mr. Blyth. I placed them in a breeding-cage, and, to secure them from rats, suspended it to the ceiling of my drawing-room. We soon noticed that every night the floor of the room was covered with glow-worms, at which, never having seen them in that part of the island before, and they being of unusual size and brilliancy, we were much pleased.

At last it occurred to me why they came, and on placing the cage on the floor the onslaught on the contents was a convincing proof that *A. panthera* would never be naturalised at St. Pedro.

I could adduce many other instances of the smelling and the "perception of sound" (to phrase it), but will not intrude on your space. E. L. LAYARD

British Consulate, Noumea, New Caledonia, April 26

P.S. Since writing the above I named the subject to Père Montrousier, the celebrated French naturalist so long resident in this colony. He detailed the following experiment that he had made. He immersed a long-snouted weevil (*Octhorinus cruciatus*) so as to cover it, all but the tip of the antennæ, with a coating of wax. On presenting to it oil of turpentine it became violently excited and endeavoured to escape. Another now had the tips of its antennæ only coated with the wax, and neither turpentine nor any other strong smelling substance at all affected it. He places the faculty of the "perception of sound" equally in the antennæ. Since the discovery of the telephone who shall say to what extent these delicate organs can recognise the vibrations of the air? And after all, what is our own "perception of sound" but the appreciation of a vibration? E. L. L.

On the Lichen Gonidia Question

THE morphological side of Schwendener's theory may be now regarded as fully proved. The opponents have confined themselves on the whole to *à priori* arguments, and of those who have applied themselves to carefully working out afresh the relations of hypha and gonidium, several, if not all, have been converted to the new views. No one can have much faith in the haphazard style of preparation and examination known, *par excellence*, as the "lichenological." However, one or two points remain which have not as yet received much attention. These are the beautiful symmetry of the lichen as a whole, the rareness of the application of the hypha to the gonidium, and the generally healthy look of the gonidia themselves. All this contrasts greatly with what we find, as a rule, in the relations of parasitical fungus and host.

With regard to the first objection I may call attention to the equally beautiful and symmetrical forms we find in galls, such as the spangles of the oak, the rose bedeguar, and the exquisite rosettes of certain *Dipterocarpeæ*.

It is, however, well known that many of the lower fungi can build up their protoplasm and live perfectly, if in addition to the salts needed for the growth of all plants (including nitrates or ammonium salts), there be present a tartrate or sugar. Now the gonidia, like the algæ with which they correspond, excrete as a cell-wall a thick layer of gelatinous consistency but giving reactions which show it a form of cellulose. It is in contact with, or through this that the hypha ramifies, and from this it can take up the necessary complement of the mineral food supplied by the substratum and medium. It can grow freely; and the gonidium, with its protoplasm intact, can go on growing as comfortably as the oyster infested by *Clione*. Perhaps like the oyster it may be stimulated to a more active secretion of envelope, but its health is unimpaired. Hence, too, there is no physiological need for the hypha to come in contact with the gonidia, and the last argument of the old school becomes untenable

Owens College, Manchester MARCUS M. HARTOG

The Phonograph

IN experimenting lately with the phonograph it occurred to me to try whether, after a series of musical or articulate sounds have been recorded, other series could successively be superimposed on the same tinfoil and reproduced. I found that if the instrument be simply reset to the starting-point, and sung or spoken to a second time, it will afterwards faithfully reproduce both series of sounds as though two persons were singing or speaking simultaneously, and by repeating the same process, a third and fourth voice may be added, or one or more instrumental parts, all of which will be reproduced. This experiment forms a striking commentary on Helmholtz's theory of the mode in which the ear recognises different tones in a chaos of sound, by analysing the compound wave, which it receives, into its component simple vibrations. Here the aggregate impressions on the tin-foil produce, so to speak, a compound indentation capable of reproducing a wave of sound which the ear can resolve into the original constituents.

Temple GEORGE P. BIDDER

Remarkable Form of Lightning

DURING a thunderstorm on Sunday afternoon, August 24, 1873, I saw a flash of lightning here exactly answering to Mr. Joule's description of "punctuation." The note of the storm in my diary says:—"Lightning and thunder very frequent but not violent. *One flash, very near, had the appearance of a chain of alternate links*, and remained visible, I should think, for half a second, gradually fading out." This persistence was, no doubt, mainly an optical illusion, but it shows the definiteness of the form. The flash was from cloud to cloud, and followed a very sinuous line, as described by Mr. Lawrence. Is not this what old books describe as "chain lightning?"

B. WOODD SMITH

Branch Hill Lodge, Hampstead Heath, July 12

OUR NEW PROTECTORATE

WE have only to do with politics in this journal in so far as they concern science; but without pronouncing any opinion on the wisdom of the action taken by our government in the Eastern question, it may not be amiss to say a few words from a scientific standpoint on the interesting territories which have just been brought into close relation with this country. To England the region included in Asiatic Turkey is in some respects the most interesting in the world. If not exactly the cradle of our family, there is good reason to believe that it is in close proximity to it; and no doubt it was one of the pathways by which the early Aryans sought their way to Europe. Historically and prehistorically, for the student of religion and the student of science, Turkey in Asia possesses features of the highest interest, and we may hope that one result of our new connection will be that our very imperfect knowledge of it in its various aspects will be rapidly filled up. Its shores—the Black Sea on the North, the Ægean on the west, the Mediterranean on the south, and, may we say, the Euphrates and Tigris rivers on the east—teem with historical associations. A careful investigation of its mountains and valleys, its rivers and numerous salt lakes, would doubtless yield the geologist a rich harvest of results, bearing everywhere as they do unmistakable evidence of former powerful volcanic action.

Asiatic Turkey, in its five great divisions of Anatolia or Asia Minor, Armenia, Kurdistan, Mesopotamia, and Syria, may be regarded as a western extension of the great central Asian plateau, with its surface much broken up by mountain chains and isolated ranges. This great plateau narrows very considerably as it approaches the Turkish territory in Asia, but increases in elevation. Here begins the Alpine region of Persia with Kurdistan; here are the lakes Urumiyeh and Van, and the sources of the rivers Zab, Tigris, Aras, and Euphrates. The table-land is broken up into and replaced by mountains, which rise to a great height, and by elevated valleys between them. On the north-east of Turkey-in-Asia both the mountain-ranges and the table-lands are united in the compact mountain-region and high table-land of Armenia, the country to the west resembling Europe in structure rather than Eastern Asia. Physically there are four divisions of this region, corresponding nearly to the divisions referred to above. The first is the elevated and mountainous table-land of Armenia, which extends in the form of a triangle between the angles of the three seas—the Caspian, the Black Sea, and the Gulf of Alexandretta on the south. Its central plain, on which stands Erzeroum, about which so much has recently been heard, rises to 7,000 feet above sea-level, and the highest peak of Ararat rises to above 17,000 feet.

The second great division is formed by the Caucasus, which is beyond the range of our present subject. The third separate mass is formed by the peninsula of Anatolia, or Asia-Minor, in the interior, a table-land of an average height of 3,000 feet, and joined to Persia by the mountain-chain of the Taurus. The Syrian mountains

form the fourth division, culminating in Mount Libanus and terminating in the isolated mountain-mass of Sinai. The whole extent of Turkey-in-Asia is estimated at 660,000 square miles, and its population variously estimated at from ten to twenty millions.

The most extensive and altogether most remarkable mountain-chain of Turkey-in-Asia is the Taurus, with its offshoot the Anti-Taurus, belonging mainly to the division of Anatolia. The Taurus begins on the east, by the Euphrates, where one of its peaks rises to nearly 10,000 feet, and runs irregularly westwards not far from the Mediterranean coast, through Caramenia and Lycia, ending in the islands of the Greek Archipelago. Both to the north and south it sends out shoots, the island of Cyprus itself being really a spur of the great mountain-mass. The northern arm, the Anti-Taurus, runs north-east; and at the Chain may be said to turn in a westerly direction along and at no great distance from the Black Sea to the Bosphorus, sending out a south-west spur culminating in Mount Olympus, near Broussa, and further south, on the Gulf of Adramyti, in Trojan Ida.

The separate portions of the Taurus inclose many plains and valleys, which lie terraced above each other in the line of the meridian. On the south side of the mountain lies the plain, formed from augitic rocks, of Diarbekr in Kurdistan, 1,800 feet above sea-level; in the middle of the Taurus is the cultivated valley of Alendah, and Lake Gorjik Gol, 4,000 feet high; on the north side is the plain of Liwas, 4,000 feet, and that of Baulus, 3,000 feet, above sea-level, from which the land sinks rapidly to the Black Sea. In the south-east part of the peninsula rises the isolated peak, having little connection with the main range, the Erdjas Dag—the Mons Argæus of the ancients. It stands on the plain of Kassarieh (Cæsarea), its foot being 3,300 feet above sea-level, and its summit, the culminating point of Anatolia, close on 13,000 feet above the sea. It consists entirely of volcanic products, and its summit contains two craters, long ago extinct. The whole inner plateau, west to near Kutaya and thence to the plain of Sardis and even to the west coast at Smyrna, bears evident traces of volcanic activity. Extinct volcanic cones, often of considerable height, lava-streams and other unmistakable signs of subterranean activity, extend over a considerable space. Earthquakes are of frequent occurrence, and warm sulphur springs are numerous in Anatolia.

In the Anatolian peninsula the rivers flow mostly north-westwards into the Black Sea, though the courses of not a few of them remain to be explored. The most considerable of these is the Kisil-Irmik (the ancient Halys), though one of the most interesting is the Mendereh (ancient Meander), celebrated for its luxurious valley and winding corners, and for the fact that since Homer sang of it, the action of its current, combined with the action of the sea, has altered the whole aspect of the coast about Besika Bay.

The climate of Asiatic Turkey presents so many variations on account of the great inequalities of its surface, that any general view of it is impossible. In one day the traveller may go from the cold of winter to a heat almost tropical, and *vice versâ*. In the Mesopotamian and Bagdad regions, at the head of the Persian Gulf, and along the banks of the Tigris and Euphrates the heat in summer is quite tropical. Sir Frederic Goldsmid in his "Telegraph and Travel," a work which contains many valuable notes on the features and condition of the country in 1864, found it average 96° in the shade near Mosul in the beginning of June.

The Anatolian peninsula gradually blends eastwards into the highlands of Armenia, which unite the mountains of Asia Minor with the great system of Central Asia, and give rise to the two great rivers of Asiatic Turkey, the Euphrates and the Tigris. Armenia is a land of terraces. Between the rivers rise dividing mountain-ranges; within and between these ranges are wide, mostly level, steppe-like plateaux of various heights, which lie like terraces over each other; deep-cut valleys, gloomy, towering mountain masses; extreme climate, with severe winter and dry hot summer; in the valleys and on the mountain-slopes luxurious vegetation, but scanty on the plateaux; on the eastern border the landscape is Alpine, and forms the immediate connection between Armenia and the great table-land of Iran. The Armenian mountains are continued southwards into Kurdistan, gradually shading off into the great plain of Mesopotamia. In the north of Kurdistan lies the romantic salt lake Van, 1,200 square miles in area, at a height of 4,000 feet above sea-level. The two streams which water Mesopotamia, the Euphrates and Tigris, have a generally parallel course, sometimes approaching and sometimes receding from each other. At Bagdad they approach most closely before uniting, not far above the outlet in the Persian Gulf, giving the included land the shape of an hour-glass. It was this included land which the ancients appropriately named Mesopotamia, the northern half being now known as El Jesireh, or the island, and the southern Irak Arabi, or the Arab Irak, to distinguish it from the neighbouring Persia, or Irak Ajemi. The delta of the united stream begins about forty miles above its outlet, and there is evidence that since the time of Alexander the Great, the land must have encroached considerably on the Gulf. Lying between Mesopotamia and the coast region of Syria, and its southern part, Palestine, is the great Syrian desert, a chalk plateau of about 1,800 feet above the sea, bound on the west side by a great depression.

The flora of Asiatic Turkey, as might be expected, is very varied, partaking of a combined temperate and sub-tropical character. As to its fauna, the lion has disappeared from the countries west of the Euphrates, while in Mesopotamia are found the hyæna, panther, buffalo, and wild boar; jackals, bears, wolves, and wild hogs are met with in Asia Minor. The leopard is still found in the interior of Palestine, the Syrian bear in Lebanon, while European animals are found nearly everywhere. The whole territory is included in the Mediterranean sub-region of the Palæarctic Zoological region. (See Wallace's "Distribution of Animals.")

With regard to Cyprus a volume might be written on its history, from the time of the Phœnicians (it is supposed to be the Chittim of the Old Testament) till now, and we quite recently noticed Gen. Cesnola's remarkable work on the antiquities of the island. The ancients appropriately compared the shape of the island to that of a deer's skin or a fleece spread out. In length it is about 140 miles, and about 45 in breadth, much about the size of Skye and the Long Island from Barra Head to the Butt of Lewis together. The centre of the island is a plain or table land, while mountain-ranges occupy the west and south-west, and the northern coast is mountainous along its whole extent. In the northern range the highest summit does not exceed 3,340 feet, while among the southern masses, Mount Olympus (Trodos or Troödos) reaches a height of 6,590 feet. Other summits range from 2,000 to 5,000 feet. In the time of Titus a volcanic outburst from the northern range did great damage, and destructive earthquakes seem to have been at one time frequent. The streams are few and small; rain is almost unknown from May to October; the heat of summer is excessive on the plains, though the winter is mild, and the climate on the whole may be regarded as healthy. At one time the island appears to have been thickly wooded and to have yielded valuable mineral and vegetable products. The island is said to have then sustained a population of a million, but now the inhabitants do not exceed 180,000. Speaking of the flora of the island Drs. Unger and Kotschy in their work "Die Insel Cypern," say:—

"In Cyprus prairie or meadow land does not exist; the

'Ackerland' takes the place of it. After the rains, but only for a short time, cereals give a satin-like green to the landscape; and among them grow a profusion of flowers; but these artificial rather than natural fields fade more quickly than the flowers, and scarcely last a few weeks beyond the last spring rain. There is only one small corner of the island where the vegetation resembles ours. The great heat of the summer destroys all the tender plants; only those plants survive which through their anatomical construction, or hard substance, or in consequence of growing near water, can resist the effects of the heat.

"There is great resemblance in the vegetation throughout the island to the Mediterranean. In February and March there is on all the river edges a profusion of lilies; in April and May on the land side is one carpet of flowers. During the heat, however, the land assumes a yellow tint. Pine forests abound, olives, myrtles, and laurel trees. As far as the island has as yet been explored we know that there are 1,000 different sorts of plants. No eastern island can show such a rich forest growth as Cyprus.

"The *Pinus maritima* in Cyprus covers the hills and mountain regions to the height of 4,000 feet as one of the commonest trees. The *Pinus laricio*, which covers all the heights to 4,000 feet above the sea, rises on the western mountains of the island to 6,000 feet, and gives it a dark appearance from the sea. The wild cypress (*Cupressus horizontalis*) is the third tree which grows commonly in the eastern part of the island and in some places forms by itself whole woods. On the whole of the northern chain of mountains this wild cypress grows often to the height of from 2,000 to 3,000 feet above the sea. Great forests of wild cypresses must also have covered the whole of the south of the island, as also a shrub, the *Juniperus phœnicea*. In the north several varieties of oak are found, and throughout the island the arbutus abounds; the carob-tree and olive flourish on the banks of all the rivers and up to an elevation of 1,000 feet above the sea."

Dr. Unger's work gives a catalogue of the fauna of the island, which includes a considerable number of troublesome insects. Copper, gold, silver, and precious stones were at one time found in considerable quantities, and the mineral resources of the island are probably capable of great development. Doubtless one of the first cares of the new proprietors will be to obtain an accurate survey and estimate of its resources.

No less important than the physical are the ethnical conditions of the vast region to which we have just undertaken the responsibility of introducing the blessings of good government. Indeed, from the administrative point of view, a correct knowledge of the inhabitants of any country is almost more necessary than is that of their outward surroundings. Yet the most profound ignorance too often prevails regarding the affinities and characteristics of the peoples, the direction of whose destinies has been either assumed or thrust upon "the Mother of Empires." How few of our Indian administrators have yet succeeded in grasping the difference between *Aryan* and *Dravidian*, not to speak of *Kolarian*, and how many still affect to speak collectively of all the natives as "Niggers"! If it is so with a country which has been under British rule for upwards of three generations, no very general or accurate knowledge can be expected of the ethnography of Asiatic Turkey, with which our relations have hitherto been of a purely commercial character. Hence no apology will be needed for here submitting a few notes on the subject, for which we are indebted to Mr. A. H. Keane, B.A.

Apart from the question of the Autochthones, if any still survive, three distinct stocks are at present in possession of Turkey-in-Asia, taking the term in its widest sense, so as to include parts of the Arabian peninsula, as well as Syria, Mesopotamia, Armenia, and Asia Minor proper. These stocks or racial families are the Ural-Altaic, Aryan, and Semitic, each of which, omitting such minor distinctions as Juruks, Gipsies, Samaritans, Nestorians, Chaldæans, may be said to be represented by three separate offshoots, as clearly shown in the subjoined scheme. Here the various nationalities are grouped in the first, second, and third columns, according to their ethnical, linguistic, and religious connections respectively, while in the fourth an approximate estimate is given of their numbers, say twenty millions altogether.

		Language.	Religion.	Population.
I. Ural-Altaic Stock.	Turks	Turkish	Muhammedan	12,000,000
	Turkomans ...	Tatar dialect...	Muhammedan	300,000
	Kysyl-Bashes	Turkish	Pagan	?
II. Aryan Stock.	Hellenes ...	Greek	Orthodox and United Greek	2,000,000
	Armenians ...	Armenian ...	Orthodox and United Armenian ...	3,000,000
	Kurds	Kurdish; Zaza	Muhammedan mainly... ...	1,000,000
III. Semitic Stock.	Arabs	Arabic	Muhammedan	1,500,000
	Maronites ...	Arabic	United Syrian	30,000
	Druses	Arabic	Pagan	40,000

Mention should also be made of the few Circassians still surviving of those who, some years ago, fled from the sword of the Russians, and of the few thousand Lazes still left to Turkey by the Berlin Congress. Both belong to the southern branch of the CAUCASIAN STOCK, which is entirely distinct from any of the foregoing. Nor should the Jews be overlooked, who, though still numerous in some of the larger cities (10,000 in Jerusalem alone), have almost disappeared from their original homes.

But of the really representative peoples in these regions the Turks are undoubtedly entitled in every respect to our first consideration. Anatolia, that is to say, all the country between the Upper Euphrates and the Ægean Sea, and from about the 36th parallel northwards to the Euxine has for centuries been the true home of this race. Although even here intermingled in the west with the Greeks, in the east with the Armenians, Kurds, and Arabs, they form, on the whole, the great bulk of the population of Asia-Minor within the specified limits, presenting a compact and homogeneous mass—homogenous in every sense of the word, in race, speech, and religion. They are unquestionably of pure Tataric descent, their Muhammedan prejudices having enabled them to keep aloof from the surrounding populations ever since they entered the country as conquerors in the eleventh century. Hence it is that Anatolia has long been the true backbone of the Turkish rule, a backbone reaching even across the Bosphorus, and that in Anatolia alone is it possible profitably to study the true character of the Osmanlis.

Doubtless the word "Turk" itself is now eschewed in Asia-Minor, where it has become almost a term of reproach corresponding to our "clod-hopper" or "yokel." But this simply means that the Anatolian Turks have become essentially a rough peasant people, as contrasted with their more refined kinsmen of Roumelia and Constantinople. It would be difficult to imagine a greater contrast than is presented by the Asiatic and European branches of this race, though it is of the last importance that the difference should be thoroughly realised before a just estimate can be formed of the Turks as a factor in the calculations of statesmen. They have, unfortunately, been too often judged from the polished and somewhat effeminate Effendis of the Capital, as many superficial observers are apt to confound the gay, frivolous *jeunesse dorée* of the Paris boulevards with the plodding and really thrifty agricultural people of France.

The Anatolian Turks are a lusty, stalwart race, of rude manners and harsh utterance, still speaking nearly in its purity the primitive agglutinating Turkish tongue, which in Stambûl has become a sort of Arabo-Perso-Tatar medley. They are not, perhaps, over-industrious, cultivating little more than is needed to supply their modest wants, and showing a preference for the fig, the vine, and the olive, plants yielding bounteous returns for the little care bestowed on them. Though by constitution extremely frugal, with few and simple belongings, and living in the humblest of dwellings, they are still generally oppressed with debts, and at the mercy of the usurer and the tax-gatherer, the former relentlessly exacting his pound of flesh, the latter often farming the public revenues, forestalling the tithes before harvest-tide and basing his estimates on calculations not always realised even in more favoured climes. Hence many yearly give up their holdings, sinking to the position of proletariates, the day-labourer's life being in many respects preferable to that of the small tenant farmer left unprotected by the authorities and an easy prey to the unscrupulous in a country where the administration of justice leaves much to be desired.

Fortunately for their rulers, past and to come, the Anatolian Turks are a patient, much-enduring race, kindly, hospitable, and tolerant in religious matters. Of an earnest, taciturn temperament, with much sound understanding and shrewd observation, they are yet devoid of foresight and business habits. Hence they make, as a rule, indifferent merchants, so that most of the wholesale trade has fallen into the hands of the rival races. In the country districts they are simply tillers of the land and stock-breeders, in the towns dealers in small wares mostly of home production, or else craftsmen employed in such industries as are needed to supply the few wants of Turkish life. Their seafaring qualities, however, have been unjustly decried, for in the hands of efficient officers they make excellent sailors, while as organisers and conductors of caravans they are unsurpassed. Their greatest shortcomings are perhaps a certain apathy due mainly to the universal belief in *Kismet*, or "the Inevitable," combined with the absence of progressive ideas and indifference to the future. Heedless of the morrow they will often pay exorbitant interest to escape from present pressure. Hence where mingled with other peoples they have fallen somewhat behind in the race, though never sinking to abject want, so modest are their needs, so rich their lands in varied resources. Military service, also, as is well known, weighs heavily on them, and on them alone, helping with polygamy, and all its accompanying evils, to account for the steady decrease of the Turkish element for some years past, especially on the coast.

Here the somewhat indolent Osmanli has had to confront the more versatile Greek, still clinging to his old Ionian homes along the eastern shores of the island-studded Ægean, and it is not, perhaps, surprising that under such circumstances his quick-witted rival has largely succeeded to his inheritance. For the second time in the history of the Hellenic race, *Græcia capta feros victores cepit.* An industrious trader, a shrewd calculating merchant, an excellent seaman, an intelligent agriculturist, the Greek outstrips the Osmanli in his own special province, while monopolising the learned professions. Smyrna has thus again become a Greek city, and the Greek race has in modern times everywhere displayed a praiseworthy zeal for the spread of education, while fostering among the people a healthy national sentiment. A well-directed and widely-ramifying association, radiating from Athens, encourages a movement which has tended more than anything else to maintain the influence of the Hellenic race in western Anatolia, despite their numerical inferiority.

Next to them in importance are the Armenians, sparsely diffused throughout the east from Constantinople to Calcutta, and still existing as a distinct nationality in the north-eastern highlands of Anatolia. Intellectually almost on a level with the Greeks, out-rivalling them in commercial enterprise, the Armenians present certain distinctive physical, social, and moral characteristics by which they are readily recognised wherever met. Conspicuous amongst these traits, besides their speech, belonging to the Eranian branch of the Aryan family, are their national dress, their bushy close-set eyebrows, and a decidedly unlovable disposition, which has earned for them the dislike and contempt of their neighbours. Their trickery and avarice have become proverbial throughout the East, and after making all due allowance for exaggeration, they cannot be altogether acquitted of a certain moral obliquity. Deprived for generations of all political rights, they have taken eagerly to trade like the Jews in Europe, like them in many places monopolising it, ruling the money market, and notwithstanding mutual family jealousies ever ready to band together and make any sacrifices for the common good. As traders they certainly display an amount of keenness and cunning, though of a somewhat low order, dealing by preference in "the cheap and nasty," and retailing their "shoddy" and "Brummagem" wares at exorbitant prices to an ignorant *clientèle.*

Constitutionally timid and reserved they may on the whole be regarded as a feeble race, rarely appealing to arms in self-defence, in all cases ever ready to yield submission to the strongest. Of all Christian peoples the Armenians harmonise best with their Turkish rulers; they habitually speak Turkish like a second mother-tongue, and come nearest to the Osmanli in their quiet, earnest disposition.

Of far different temperament are their southern neighbours, the fierce, freedom-loving Kurdish highlanders. Long recognised as belonging also to the Eranian branch of the Aryan stock, in which they seem linguistically to approach nearer to the Persian than to the Armenian sub-division, the Kurds have been variously depicted, according to the sympathies of the writer, as brave, chivalrous mountaineers or else treacherous, lawless, and blood-thirsty marauders. All, however, agree in describing them as of a restless and unruly disposition, some attributing this quality to the effects of Turkish misrule, others to inherent national temperament, the latter appealing with some plausibility to the sentiment of antiquity, according to which the fierce *Carduchi* of Xenophon evidently bear a strong family likeness to their modern descendants.

What may be called the disturbing element in Asiatic Turkey is continued from Kurdistan southwards to Arabia by the Bedouins of the Syrian desert. Half savage Kurdish tribes in the uplands about the head streams of the Tigris and the Euphrates, almost equally restless nomad Arab tribes in the plains watered by those rivers will for a long time tax all the watchfulness of a strong and wise administration. Nominally subjects of the Porte, the Shamara, Beni-Lam, and other powerful Arab tribes have long maintained an ill-disguised standing feud with the authorities, often making their presence unpleasantly felt, especially along the right bank of the Euphrates from about the parallel of Aleppo all the way to the Persian Gulf. If united they might easily bring from 10,000 to 20,000 formidable mounted warriors into the field. But here as elsewhere tribal dissensions neutralise their power, enabling the Turks still to keep the upper hand in the Mesopotamian plains, and show a fair front towards the Persian frontier.

A glance at the population column in the above scheme will show at once that the peoples hitherto touched upon —Turks, Greeks, Armenians, Kurds, Arabs—can alone possess any real importance for the future administrators of these regions. The Kysyl-Bashes, Juruks, Druses, and Maronites, doubtless present many curious problems

to the ethnologist and philologist. But they are numerically too insignificant to claim further notice here.

The Island of Cyprus presents no fresh ethnical elements beyond those specified in our scheme. The bulk of the population are Greek, or, at all events, a mixed Phœnician, Carian, and Greek people that have long been Hellenised. The rest are mainly Turks, and both have hitherto been permitted to live harmoniously together. They are not likely to prove a source of trouble to their new rulers.

As to the future of this varied and interesting region, it is not for us to speak. Everywhere there are evidences that at one time it must have been thickly populated and its resources highly developed. What the country is capable of may be learned from the classical reports of Palgrave, Scherzer, and other British and foreign consuls, as well as from the various special reports on the much-talked-of trans-Asiatic railway. In this connection books worth referring to are Palgrave's "Essays on Eastern Questions," Goldsmid's "Telegraph and Travel," and Goldsmid and Blanford's "Eastern Persia." Good authorities to consult on the geography and science of the region are the various articles in the "English Cyclopædia," recent volumes of Petermann's *Mittheilungen*, Hellwald's "Die Erde und ihre Völker," the *Bulletin* of the French Geographical Society, Chihacheff's "Asie Mineure," Schliemann's and Cesnola's works, Thielmann's "Caucasus, Persia, and Turkey," Unger's "Die Insel Cypern," besides older well-known works.

TYCHO BRAHE'S CORRESPONDENCE[1]

We have received the first three *fasciculi* of this work, projected by M. Friis in 1876. Its purpose is to place in the hands of the astronomer, in a collective form, the letters of Tycho and his correspondence, preserved in the Royal Library at Copenhagen, and in the libraries of Vienna, Pulkowa, and Basle, and others which may be found elsewhere, and it is expected that the work will be complete in about sixteen parts. The earliest letter is one from Tycho to Joannes Aalborg, afterwards librarian at Copenhagen, dated January 14, 1568. There are letters to or from Steno Bille, or Bilde (an uncle of Tycho's, at whose house, it may be remembered, he detected the celebrated star of 1572 which is associated with his name), Thaddæus Hagecius, physician to the Emperor Rudolph II., Paulus Haintzel, Hieronymus Wolfius, and others, whose names occur in the well-known treatise, "De Nova Stella Anni 1572." In a letter, No. 47, written in 1584, to Henricus Brucæus, Tycho enters into some discussion of the "Hypothesis Copernici," in another to Hagecius (we follow the Latin names in use at the time) he refers at length to the parallax of the comet of 1577, observed by him with much care; from his observations of this body, as Pingré says, "on en concluait que le lieu des comètes était au-delà du ciel de la Lune."

The third part contains a finely-executed portrait of Tycho (Woodburytype) from the oil painting in the possession of Dr. Crompton, of Manchester, for information respecting which M. Friis refers his readers to NATURE, vol. xv. p. 406, and vol. xvi. p. 501; an account of it also appeared in the *Proceedings* of the Manchester Literary and Philosophical Society, October 31, 1876.

We may express the hope that the success attending the publication of the first three numbers of this work may be sufficiently encouraging to induce a more rapid issue of the remaining parts.

[1] "Tychonis Brahei, et ad eum doctorum virorum Epistolæ nunc primum collectæ et editæ," a F. R. Friis. (D. Nutt: London.)

OUR ASTRONOMICAL COLUMN

PERIODICAL COMETS IN 1879.—Of the known comets of short period, two will pass through perihelion in the spring of the ensuing year. The comet discovered by Brorsen at Kiel in February, 1846, and since observed in 1857, 1868, and 1873, according to the elements deduced at the last appearance by Dr. Schulze, will arrive at perihelion again on April 1, perturbations, which must be light in the actual revolution, being neglected. This comet still approaches very near to the orbit of the planet Jupiter, though perhaps not quite so close as in 1842, when the present form of orbit was impressed upon it by the action of the planet, the point of nearest approach being at a true anomaly of 167° 48′, or in heliocentric longitude 283° 30′ (Eq. 1870); when last passing this point of its orbit, early in October, 1875, Jupiter was distant from the comet, 5·58, whence the effect of his attraction upon the length of the present revolution will be comparatively trifling. At the ascending node the comet may approach pretty near to Venus, as was the case in October, 1873, a few days previous to the last perihelion passage. To obtain an idea of the track in the heavens in the spring of next year, we may assume that the comet will arrive at its least distance from the sun at midnight on April 1 (guided by Schulze's elements) and will have the following positions:—

12h.	R.A.	N.P.D.	Distance from Earth.	Distance from Sun.	Intensity of Light.
March 12	23·6	89·7	1·35	0·71	1·08
,, 22	32·4	80·5	1·20	0·63	1·77
April 1	41·6	69·7	1·05	0·59	2·58
,, 11	51·7	57·5	0·91	0·63	3·06
,, 21	63·3	45·9	0·81	0·71	3·00
May 1	85·0	33·3	0·74	0·83	2·66
,, 11	118·6	27·2	0·71	0·96	2·12
,, 21	154·2	30·8	0·74	1·09	1·53
,, 31	176·3	40·1	0·81	1·23	1·02
June 10	189·0	50·2	0·91	1·36	0·65

Whence it may be expected that the comet will be observed in the latter half of March, attaining its greatest brightness as it traverses the constellation Perseus, about the middle of April.

The second comet due in 1879 is that discovered by M. Tempel at Marseilles in April, 1867, and re-observed in 1873, after undergoing great perturbation from a close approach to the planet Jupiter, early in 1870. The best elements for 1873 are those of Sandberg, according to which the next perihelion passage would fall on April 26, without taking into account the effect of planetary action, which, as in the case of Brorsen's comet, is not likely to be material in the present revolution; indeed, when the comet was last in aphelion, and nearest to the orbit of Jupiter, the planet was on the opposite side of the sun.

Assuming, then, that the next perihelion passage will take place at midnight on April 26, the following positions and distances will result:—

	R.A.	N.P.D.	Distance from Earth.	Distance from Sun.	Intensity of Light.
April 26	261·8	106·5	0·916	1·770	0·38
May 16	262·9	109·3	0·819	1·778	0·47
,, 26	262·1	111·0	0·796	1·789	0·49
June 5	260·7	112·6	0·791	1·804	0·49
June 15	259·1	114·5	0·808	1·823	0·46

The comet under the above condition, will therefore be situate during the whole period in the southern part of the constellation Ophiuchus, and it may be hoped that it will be well observed, as, during the ensuing revolution, material perturbations of the elements may be again occasioned by the action of Jupiter, from which body the comet at the beginning of October, 1881, may not be distant more than 0·55, a degree of approximation that, although not sufficient to lead to such heavy disturbance of the comet's motion as in 1870, will yet render a precise determination of the orbit in 1879 very essential for an accurate prediction of the apparent track in 1885.

In September, 1879, another return of Biela's comet will be due with the elements of 1866, but we reserve a few remarks upon this subject for another note.

A New Comet.—By telegram to the Vienna Academy of Sciences, with which body rests the award of the medal for cometary discoveries, it is announced that a telescopic comet was detected on July 7 by Mr. Swift, of Rochester, N.Y. The place at 14h. was in R.A. 265° and N.P.D. 72°, if the telegram is to be read according to the suggestion of the late Prof. Littröw; the comet was a faint diffused object, and had a slow motion towards the south-west.

It would be an advantage if arrangements could be made for the communication of telegraphic notices of these discoveries to the Royal Astronomical Society, which is the proper centre for such information in this country.

Minor Planets.—On June 26 Prof. Peters detected No. 188 in R.A. 15h. 37m., N.P.D. 106° 18′, shining as a star of the twelfth magnitude. No. 173, discovered by Borrelly on August 2, 1877, has been named *Ino*, and No. 180, which was found by Cottenot on February 2, 1878, it is proposed to call *Eucharis*.

Saturn's Satellites.—Mr. Marth has again prepared, evidently at great trouble, ephemerides of the five inner satellites of Saturn, which will be found in Nos. 2,205-6 of the *Astronomische Nachrichten*, as far as October 23, the conclusion to follow. With such elaborate prediction, the regular observation of these faint objects should be assured; indeed Mr. Marth's exertions in this direction have already led to excellent results.

BIOLOGICAL NOTES

The Male of Salpa.—The development of the spermatozoa in the Salpæ has hitherto not been satisfactorily studied. Only two years ago Mr. Brooks, of Boston, stated that the testis developed from the elæoblast, and moreover maintained that of the two generations which alternate in these pelagic Tunicates—the one set, the "chain" Salpæ, are exclusively males, whilst the other set, the "solitary" Salpæ, are exclusively females. This view involved the theoretical assumption that the single egg which is found in every individual of a chain of Salpæ does not *really* belong to that individual which is only a male, and has the egg laid into it by the solitary Salpa from which the chain is derived by budding. Accordingly, the elæoblast in the solitary Salpa which, according to Brooks, is female, represents the testis and points to a primitive hermaphroditism; whilst in the chain Salpæ (actual males, according to Brooks), the elæoblast becomes testis. The more usual view is that the solitary Salpæ are not sexually differentiated at all, and that the chain Salpæ are hermaphrodites. Prof. Salensky, of Kasan, has recently published (*Zeitsch. wiss. Zoologie*, 1878, Supplement 2) some observations on this matter, having previously given a very careful account of the development of these organisms, and at the same time he enters into a discussion of the relationships of various Tunicata which has much interest. He shows that the eggs found in the chain Salpæ cannot be regarded as given off from the solitary mother into the budded chain because there is no specialised ovarian cord or rudiment in the proliferous mother. She differs in this respect from the adult proliferous persons in Pyrosoma—which really, as shown by Huxley and by Kowalewsky, give to their buds a part of their own ovarian rudiment. The solitary Salpa has nothing of the kind to give. Further, Salensky shows that the elæoblast has nothing to do with the testis. It exists in the solitary Salpa, and in the chain Salpa appears only for a brief period, and then disappears; but is certainly *not* developed into a testis. Accordingly the solitary Salpa is devoid of all trace of either ovary or testis. The elæoblast appears very probably, according to Salensky, to represent the notochord. The tailed larvæ of the true Ascidians possess a well-developed notochord, and present to us the ancestral form of the Tunicata, which only persists to the adult condition in the Appendiculariæ. In the Ascidiæ the tail and notochord atrophy as development advances. In Doliolum the young form which develops from the egg has a short tail with an axis apparently intermediate in character between the notochord of the Ascidian tadpole and the elæoblast of the Salpæ. The sexual form of Doliolum developed by budding from a second sexless generation, is devoid of tail. Salensky holds that we must distinguish in the Tunicata such simple budding from the adult as is presented in the Pyrosoma colonies and others, and that kind of budding which definitely characterises the alternation of generations morphologically distinguishable from one another. The sexless nurse, constituting the one generation, appears to retain the characteristics of the ancestral Tunicate form with tail and notochord. It corresponds to the Ascidian tadpole, and is represented in more or less completely modified condition by the tailed sexless nurses of Doliolum, by the solitary Salpæ, and by the Cyathozooid or primary person of the Pyrosoma colony, which gives rise to the colony by a process of budding which it is necessary to distinguish very widely from that which the persons of the colony exhibit at a later stage themselves. Just as the Ascidian tadpole becomes itself atrophied and metamorphosed so as to form the sexually mature Ascidian, so do the "nurses" above mentioned give rise by budding to a generation not possessing their own archaic characters, but bearing sexual organs and corresponding to the adult Ascidian, and thus we have an alternation of form in the successive gamic and agamic generations. Should multiplication by budding or fission be confined to the later sexual phase, then there is no morphological alternation of generations. Salensky thinks that a hopeful way of gaining a deeper insight into the phenomenon of true metagenesis lies in the further study of the cases presented by Tunicata. E. R. L.

The Structure and Development of Sponges.—The sponges are at present attracting a very large amount of attention from zoologists and are undergoing investigation in the fresh condition, so that their living soft tissues are subjected to the refined methods of modern histology. Prof. Franz Eilhard Schulze, of Gratz, is foremost in this study, the way in which was led by Ernst Haeckel in his monograph of the Calcispongiæ. Dr. Keller, of Zürich, who has previously published on the development of certain calcareous sponges, has now (*Zeitsch. wiss. Zoologie*, 1878, part 4) given attention to *Reniera semitubulosa*, O. Schm., a representative of the commoner marine fibrous sponges. Schulze, by the use of silver nitrate, discovered a differentiated epithelial covering to the body surface, which was previously denied by Keller, who now admits Schulze's observation to be correct, and adds a similar observation of his own on Reniera. Keller describes the syncytium of Reniera, denies the existence of muscular cells, and recognises certain "nutritive wander-cells" in the body-wall of the sponge. His observations on "starch-containing cells" are of special importance. He was led to attach a high functional importance to the nutritive wander-cells which pass inwards from the flagellate endoderm-cells, carrying with them assimilated matter necessary for the nutrition of the syncytium, which forms a thick wall beyond. His conception of their importance was confirmed by the discovery that many of them contain starch. Keller has made an extensive search for starch in the cell-elements of sponges, and has found it, or rather we should say has obtained the blue reaction with iodine, in cells from the following sponges:—(1) *Spongilla lacustris*, (2) *Reniera litoralis*, nov. spec., (3) *Myxilla fasciculata*, (4) *Geodia gigas*, (5) *Tethya lyncurium*, (6) *Suberites massa*, (7) *Suberites flavus*. The substance, whatever it may be, which gives the blue reaction, is not in a granular condition, but fluid, and in those cells in which it occurs occupies a large vacuole comparable to a fat vacuole. Neither ordinary nor absolute alcohol, nor

cold water, dissolve the contents of this vacuole. Keller could not find this starch-like substance in Halisarca nor Chondrosia, nor in any Calcispongiæ. It seems desirable in this connection to refer to the strictly granular condition in which chlorophyll appears in the case of Spongilla, the granules having the form of concavo-convex discs. In colourless (etiolated) specimens of Spongilla, the same granules are present of a little different form, and as in Neottia and other similar plants, these granules turn green (develop into chlorophyll?) on the addition of strong sulphuric acid (see *Quarterly Journal of Micros. Science*, 1874, vol. xiv. page 400, where I have recorded these facts, and also that of the occurrence of starch in Spongilla, though I have not yet been able to find the authority for the latter observation, which was made many years previously to Keller's investigation). With regard to the question of the formation of a gastrula in Sponges, and as to the development of the endoderm of that gastrula into the endoderm of the adult sponge, and therefore the continuity of the archenteric cavity of the gastrula with the digestive cavity and canals of the sponge, Keller has some remarks to offer which do not, in point of fact, amount to very much. Like Franz Eilhard Schulze, Keller fell into a complete error in his earlier publication on the development of Calcareous Sponges. Haeckel, in his monograph, stated that the sponge embryo was at first a hollow one-cell-layered sac, on the inner wall of which a second cell layer formed, by delamination, whilst subsequently a mouth broke through. This was vehemently denied and ridiculed by Metchnikoff; it was also denied by Oscar Schmidt, and by F. E. Schulze, who published a beautiful set of drawings showing that after the embryo sponge had acquired some thirty or forty cells, one hemisphere of cells became granular and enlarged, and then invaginated—sunk into the other hemisphere—thus forming a gastrula with endoderm and archenteron by invagination. This account was at first accepted as the true one, but it was strongly insisted upon by Keller in his former memoir, that the orifice of invagination closes up, as in fact the blastopore so usually does throughout the animal kingdom, and that the young sponge is then a mouthless closed sac with two layers of cells. It was in this condition that Haeckel saw it and described the further stage in which the true mouth breaks through. There is, however, still a great difficulty about the development of the gastrula of sponges; for no one can doubt, who will examine a common calcareous sponge, or who looks at Barrois' valuable memoir on the subject, that F. E. Schulze was—as he himself has admitted—so far misled in his account of the development of *Sycandra ræphanus* as to transpose two very important stages of the development. In fact, the concavo-convex stage of the embryo sponge, with one set of cells (endodermic) tucked into the narrower, clearer, longer, ciliate cells, actually *precedes* that in which the same cells form respectively a hemisphere of clear ciliate cells and a hemisphere of large swollen cells, not tucked into the former at all, but so arranged that a small central cavity is closed in by the two groups. How we pass from this stage to the young sponge, or even to the two-cell-layered sac, is still a complete mystery. One thing, however, is obvious. Haeckel could hardly have been led to the generalisation known as the gastræa theory, which, on the whole, is a truthful and productive generalisation, by erroneous observation. We must, therefore, respect his positive statements of fact.

E. R. L.

GEOGRAPHICAL NOTES

THE Swedish North-East Passage Expedition, under Prof. Nordenskjöld, was arranged to start from Tromsoe about the 15th inst. in the *Vega*, which sailed from Gothenburg about the beginning of the month. The *Vega* is commanded by Lieut. Palander, who was second in command of the *Sofia* in the polar expedition of 1868. Nordenskjöld's scientific staff consists of F. Kjellman, docent in the University of Upsala, who took part in the expeditions of 1872-3 and 1875; Dr. A. Stuxberg, who took part in the expeditions of 1875 and 1876; Dr. E. Almquist, medical officer; Andreas Hovgaard, lieutenant in the Danish navy, physicist; and Giacomo Bove, lieutenant in the Italian navy, hydrographer, the last-named officially sent by his Government. The *Vega* is provisioned for two years, but if the state of the ice be favourable, Nordenskjöld hopes to reach Behring's Straits by the end of September. The *Vega* will be accompanied as far as the mouth of the Lena by a new steamer, the *Lena*, which will ascend the river of the same name, on which it is intended to ply, as far as the town of Yakoutsk.

AFTER an absence of several months Dr. Georg Schweinfurth returned to Cairo on June 13 from his exploring journey through the Arabian desert. He reports having crossed some fifty valleys in the desert mountains, which he entered near Atfieh; eventually he reached Mount Gharib, and later on the Nile near Siut. Dr. Schweinfurth intends returning to Europe for some time to recruit his health, which has considerably suffered.

PROF. BASTIAN, of Berlin, who has explored more or less in nearly every region of the globe, is setting out again for four years' work in Asia, and especially in Further India, from whence he hopes to bring home many additions to his already large ethnological collection.

THE long-talked-of voyage round the world, under the auspices of the Société des Voyages d'Etude, is at last coming off under the leadership of Lieut. Biard. The *Junon*, the vessel in which the expedition sails, leaves Marseilles this week. We have on several occasions alluded to this and other similar projects, very tempting but much too expensive to attract many passengers. In the present case only twenty-five student-passengers of various nationalities have been obtained. The *Junon* has on board three professors who will lecture on natural history, geography, physics, and meteorology. The expedition has been well planned, and if the programme is carried out to even a moderate extent, the young voyagers ought not only to enjoy themselves, but return with much more knowledge, and perhaps wisdom, than when they set out. The *Junon* proceeds westwards to North and South America, the archipelagos of the Pacific, Australia, and New Zealand, China and Japan, India and Egypt, returning to the Mediterranean by the Suez Canal. A considerable part of the eleven months or so the expedition is expected to be away will be passed in the various countries at which the expedition will touch.

IN No. 3 of the *Deutsche geographische Blätter* of the Bremen Geographical Society Herr Camill Russ has a long and valuable paper on the present position of Abyssinia; the author has an intimate personal acquaintance with the country. Dr. Sandeberg gives a graphic and instructive account of a pilgrimage in Russia, in the summer of 1876, to Solowjetsk, lying between Lake Onega and the White Sea, and for centuries one of the most celebrated places of pilgrimage in Russia. Dr. Bretschneider, physician to the Russian Embassy in Pekin, sends a long letter, giving detailed instructions as to the best methods and seasons for travelling through Siberia and Mongolia to China, which will be found of great service to any enterprising tourist who may have time and money enough to spare for such an out-of-the-way journey. The letter conveys indirectly a good deal of information concerning Siberia and Mongolia.

IT is stated that the Lisbon Geographical Society reports favourably on a project for an exploring expedition in Portuguese Guinea.

THE GENESIS OF LIMBS [1]

II.

In those huge marine reptiles of the secondary period, the *Ichthyosaurus* and the *Plesiosaurus*, we meet with the most complete serial symmetry between the fore and the hind limbs. In the *Plesiosaurus*, not only are the bones of the hand and foot completely alike, but the same is the case with those of the upper arm and thigh and those of the fore-arm and leg.

In the *Ichthyosaurus* there is a similar resemblance between the fore and hind limbs, with the further curious similarity that in both hand and foot the very numerous digital bones are so disposed as to indicate that the number of the digits exceeded five.

When we descend from reptiles to batrachians we again find in the tailed forms a remarkable and exceptional serial homology in the bones and cartilages of the limbs. Thus, through the great descending series of forms from man down to reptiles and efts, we find that there is one fundamental type of limb. In all such creatures the limbs are never more than four, they are divisible into two pairs, which always possess complete *bilateral* and more or less clearly marked *serial* symmetry. This serial symmetry is generally more or less disguised owing to the different uses to which the two pairs of limbs are respectively put. Yet whatever such uses and needs may be, whether the limbs be formed simply for locomotion, as in the horse; for grasping, as in the ape; for flying, as in the bat and bird; or for swimming, as in the seal and the large extinct reptiles before referred to, we find the same limb segmentation running through all in both limbs.

1. An upper limb segment (upper arm and thigh).
2. A lower limb segment (fore-arm and leg).
3. A root part of the extremity (wrist and ankle).
4. A middle part of the extremity (mid-hand and mid-foot).
5. A terminal part of the extremity (the fingers and toes, *i.e.*, the digits).

In the great class of fishes an altogether different set of conditions obtains. The parts in fishes which answer to the fore limbs of the creatures hitherto considered, are the pectoral and the ventral fins. In them we find a number of delicate structures, "fin-rays," supported by bones or cartilages which have no obvious, even remote resemblance to the bones or cartilages of the limbs of batrachians, reptiles, birds, or beasts. The pectoral limbs are indeed attached to a shoulder girdle, but the ventral fins are appended only to bones or cartilages which lie amongst the muscles of the ventral surface of

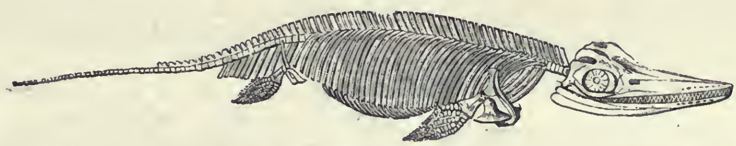

FIG. 12.—Skeleton of an Ichthyosaurus.

the body and hardly ever even approach the superincumbent vertebral column. In *Lophius*, indeed, amongst bony fishes, these supporting structures do ascend somewhat, and the same is the case in *Callorhynchus* and *Chimæra* amongst the cartilaginous fishes. Yet even here these pelvic structures are far from reaching the vertebral column.

In the fishes, which are in many respects most like the

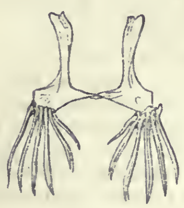

FIG. 14.

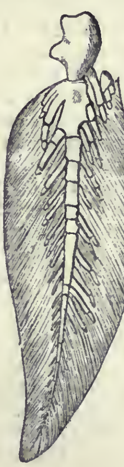

FIG. 15.

FIG. 14.—The two ossa innominata of the Angler-fish (*Lophius*), showing the ascending processes which simulate ilia. The fin-rays are attached to the outer-ventral margin of each os innominatum.

FIG. 15.—Cartilaginous skeleton of a limb of *Ceratodus*. (After Günther.) The large upper piece articulates with the limb root.

higher animals, *i.e.*, in the sharks and rays, the pectoral and ventral fins are not both formed in the same manner, but their structure differs considerably in different species.

The pectoral fin is supported by a number of cartilaginous rays which rest upon three basal cartilages lying nearest to the slender girdle and called respectively the *Propterygium*, the *Mesopterygium*, and the *Metapterygium* (see Fig. 17). The ventral fin is smaller, and consists of cartilaginous rays appended to a basal cartilage, which is suspended from the pelvic cartilage, to which latter some rays may also be directly attached.

In one very exceptional form, the ancient triassic fish still surviving in Queensland, *Ceratodus*, the limb-skeleton is *sui generis*. It consists of a median longitudinal series of cartilages, whence other smaller cartilages diverge on each side, the whole structure tapering to its distal end.

We see then, now, the answer to one of our initial questions, "What do our limbs stand for as compared with the bodies of other animals," and may proceed to another of those questions, namely, "Why are our limbs so much alike and yet so different?" We form one of a series of creatures with digit-bearing limbs (all vertebrates above fishes), all presenting similar resemblances and differences in varying degrees. The differences between our limbs are manifestly due to difference of function, but the resemblance may be due to one of two causes:—(1) The conservation of a complete serial symmetry present in the earliest vertebrate types, or (2) The action of internal polar force, tending to educe serial symmetry when such symmetry does not interfere with function. In other words, it may be due either (1) to genetic homogeny, or (2) to intra-organic homoplasy.

It appears to me impossible that it can be due to the former cause, for even if the first pairs of limbs ever formed were completely similar, which I by no means regard as certain, still the detailed resemblances found in animals high up in the scale cannot have continued uninterruptedly from such primitive forms. Even if we consider that the complete serial homology in the limbs of the tortoise, *Chelydra*, might be primitive, the limb of *Hyrax*, *Perodicticus*, and *Nycticebus* cannot owe their peculiar serial resemblances [1] to the survival of primeval conditions.

[1] Continued from p. 284.

[1] See "Genesis of Species," second edition, p. 201.

But the action of an internal polar force is evidenced by other phenomena of pathology and teratology, which come to the aid of comparative anatomy in demonstrating its existence. Thus we very often see that parts which are serially or bilaterally symmetrical, are abnormally affected in a similar manner,[1] as recorded by Sir James Paget, Dr. William Budd, Prof. Burt Wilder, and others, and the same is the case with congenital deformities.[2]

Perhaps, however, the most curious and instructive are those presented by some of our domestic birds. In birds we have found the serial symmetry of the limbs reduced almost to its minimum—the leg and foot being so widely different from the wing. In trumpeter pigeons and some bantams, however, the feet, which usually are naked, become abnormally furnished with feathers (technically called "boots"), which may be even longer than the wing feathers, and are developed from that side of the foot which corresponds with the feather-bearing side of the hand. Moreover, in ordinary pigeons, though the digits of the hand are completely united together, while the toes of the foot are free, but in "booted" pigeons the outer toes become more or less united together by skin like the fingers.

With facts such as these it seems to me unreasonable to deny the existence in each animal (which as a whole is a visible unity) of an innate polar force tending to carry out development in definite directions, but liable to have its action and effects modified by the environment.

We may now turn to those other initial questions, Whence have limbs such as ours arisen? What is a limb?

As to the first question: The digit-bearing limbs of man, beasts, birds, reptiles, and batrachians are usually supposed to have been derived from structures having more or less resemblance to the paired fins of fishes, but the path which the genetic process has followed is differently represented by different evolutionists.

As to the second question, *i.e.*, as to the essential nature of vertebrates' limbs, of whatsoever kind, different views have also been maintained. By some anatomists they have been regarded as parts which have in one way or another been derived from the axial skeleton, by others they have been represented as skeletal structures appended to, but not derived from the axial skeleton.

In 1843 Oken taught the extremely fanciful doctrine that arms and legs are so many liberated ribs, and Carus followed him to a certain extent, teaching that they are essentially elements radiating from the exterior of a rib-like arch.

In 1848 Owen propounded the view that they are diverging appendages attached to ribs like the uncinate processes of birds, and he compared them to the branchiostegal rays of fishes. He also taught that the shoulder and pelvic girdles are modified rib arches.

In 1852 Maclise represented the limbs as modified ribs, the parts beyond the elbow and the knee, however, corresponding with the interspinus bones and fin rays of fishes' azygos fins.

In 1857 Goodsir described them as radiating actinopophyses.[3]

In 1871 Humphrey represented the limbs as modified portions of a primitively continuous inferior azygos fins.

In 1872 Gegenbaur threw out the suggestions which he has since (1874 and 1876) more definitely adopted, that the shoulder girdle is a modified arch of similar nature to the branchial arches, the limbs having been formed from rays diverging outwards from such an arch. He also considers the skeleton of the azygos fins as the separated ends of the neural and hœmal spines of the vertebral column.[4]

Owen and Gegenbaur consider the paired and azygos limbs to be two fundamentally different structures, and Huxley[1] calls their sustaining bones or cartilages "elements of the exoskeleton."

The fundamental distinctness between the paired limbs and the axial system appears to have been held by Cuvier and by Huxley. I advocated the same view in 1870,[2] and I have since expressed[3] my conviction "that the appendicular skeleton is no mere portion of the axial skeleton, but a distinct system of parts appended to, and more or less closely and variously connected with, the axial system." To this conviction I now adhere more firmly than ever. I have also been long convinced that the shoulder-girdle could not be (as Gegenbaur thinks) a branchial arch, or be formed of coalesced branchial arches, as also that the branchial arches could not be (as some have supposed) serially homologous with rib-arches. For the branchial arches are within the aortic vessels, which vessels I took[4] to

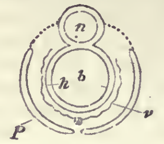

Fig. 16.—Diagram of the condition of the skeleton in the branchial region of some sharks (transverse vertical section).—*n*, neural canal; *b*, alimentary canal, surrounded by *h*, the branchial arches (splanchnapophyses); *v*, the aortic vessels, extending up outside the branchial arches and inside the paraxial system (*p*), here represented by certain external branchial cartilages.

"indicate the line of the pleuro-peritoneal division of the ventral laminæ" of the embryo. This conviction has been remarkably justified by Mr. Balfour's recent discovery of the continuation (in embryo elasmobranchs) of the pleuro-peritoneal cavity into the head, and externally to their aortic vessels.[5]

Prof. Parker has recently suggested[6] that the "extrabranchials" of the dogfish may be homologous with the scapulo-coracoid, but I am persuaded this is not the case.

In 1876 Mr. Balfour described[7] the development of the limbs of elasmobranchs as "special developments of a continuous ridge on each side, precisely like the ridges of epiblast which form the rudiments of the unpaired fins." Since then the paired fins arise in the same way as the azygos fins; they all probably belong to the same category of peripheral, non-axial structures. Moreover, since this is the mode of origin in the individual, there of course arises an *à priori* probability that it was the mode of origin in the race, and that the primeval vertebrate limbs were a pair of continuous lateral folds, serving to balance the body in swimming.

Now I conceive it will hardly be disputed that when supporting hard structures were first developed in the azygos fins they had the form they so generally still present, of a longitudinal series of numerous similar, separate, rod-like structures. But the skeleton of the paired, especially of the pectoral fins, is very different from this. The interesting questions, therefore, arise: (1) Whether any azygos fins present characters approximating them to the normally developed paired fins? and (2) Whether any paired fins present characters approximating them to the normally developed azygos fins?

A detailed account of some recent dissections of fish-fins made with a view to answer these questions—dissections effected through the kindness and liberality of Dr. Günther, at the British Museum—have been lately[8] communicated to the Zoological Society. The result of those dissections

is that I have found such varying degrees of coalescence between the cartilaginous rays of the dorsal fins as may go far to bridge over the differences between the two orders of fins, while the close resemblance sometimes presented by paired fins to azygos fins (some of the ventrals being so nearly like certain dorsal and anal fins), is such that I think a conclusion in favour of their essential similarity of nature cannot be successfully contested.

As to the dorsal fin, I have found incipient coalescence between the rays, in *Scyllian canicula*, *Ginglymostoma cirratum*, and others, but in *Notidanus cinereus* I have found this process carried to such a degree, that there comes to be one continuous basal cartilage to the dorsal margin of which the cartilaginous rays are appended.

In *Pristis* and *Pristiophorus* I found a very interesting condition which I am not aware has been described. The rays in these genera repose upon solid cartilages which are absolutely continuous with the subjacent axial skeleton. I would suggest that the lateral pressure of the saw-like rostrum must be aided in these fishes by such a firm attachment of the dorsal fin cartilages to the vertebral column. ST. GEORGE MIVART

(*To be continued*)

A HUNTING WASP

THE following interesting account of a chase between a wasp and a spider has been forwarded to us by Mr. Henry Cecil, who, it may be remembered, wrote to NATURE on the subject (vol. xvii. p. 381):—

The Piræus, Athens, June 19

DEAR SIR,—Your letter of April 5, and the two numbers of NATURE, reached this during my absence in Thessaly, which must be my apology for not having sooner replied to your letter.

Though more than thirty years have elapsed since the circumstance alluded to, I perfectly remember the curious chase I witnessed of a very large and powerful hunting-spider by a species of wasp.

I was sitting one summer's afternoon at an open window (my bed-room) looking into a garden, when I was surprised to observe a large and rare species of spider run across the window-sill in a crouching attitude. It struck me the spider was evidently alarmed or it would not have so fearlessly approached me. It hastened to conceal itself under the projecting edge of the window-sill inside the room, and had hardly done so when a very fine large hunting-wasp buzzed in at the open window and flew about the room evidently in search of something. Finding nothing the wasp returned to the open window and settled on the window-sill, running backwards and forwards as a dog does when looking or searching for a lost scent. It soon alighted on the track of the poor spider, and in a moment it discovered its hiding-place, darted down on it, and no doubt inflicted a wound with its sting. The spider rushed off again and this time took refuge under the bed, trying to conceal itself under the framework or planks which supported the mattress. The same scene occurred here, the wasp never appeared to follow the spider by sight, but ran backwards and forward in large circles like a hound. The moment the trail of the spider was found the wasp followed all the turns it had made till it came on it again. The poor spider was chased from hiding-place to hiding-place—out of the bedroom across a passage and into the middle of another large room, where it finally succumbed to the repeated stings inflicted by the wasp. Rolling itself up into a ball the wasp then took possession of its prey, and after ascertaining it could make no resistance, tucked it up under its *very long hind legs* just as a hawk or eagle carry off their quarry, and was flying off to its nest, when I interposed and secured both for my collection.

Both insects were rare ones, and during the ten years I collected as a field naturalist in Greece, I don't remember ever seeing more than three or four specimens of either that species of wasp or spider.

The wasp was a hunting one (a female) about an inch and-a-half long, a very finely formed insect, which for gracefulness of form and beauty of colouring is entitled to be placed at the head of its species. The legs of this kind of wasp are very long and of a dark chocolate brown. It runs very quickly. The wings are a light-brown with dark-brown tips and long and powerful, and the body beautifully mottled with pale yellow and brown. It has very long fine antennæ. It is not an English species, but probably exists in Spain, the south of France, and Italy.

The spider, too, was a rare one. One of the largest Greek hunting-spiders, nearly as large in the spread of its legs as the flesh-coloured tarantula though without his powerful crab-like pincers. The one I allude to must have covered at least three inches in circumference when its legs were fully extended. It was of a dull mottled brown colour on the upper surface of the body. Very difficult to distinguish from the ground. The lower part of its body was, however, brilliantly coloured, the long legs, or arms, being marked underneath with velvet-like looking black and white rings. The head, thorax, and abdomen were of a velvety black, the lower portion of the latter surrounded with a bright orange ring.

There is only one error in the account given by you in NATURE, that is, that you were under the impression I told you, that kind of spider was the common prey of that species of wasp. You must have misunderstood me.

1. I do not think that particular kind of spider is sufficiently common for this to be the case.

2. I never saw a similar conflict of the kind before or after, which as it was in a room, and not in the grass, where I presume such encounters usually take place, I observed under exceptionally favourable circumstances.

I am certain the spider left no web or thread behind it. I cannot be sure, however, that, as it had evidently been attacked by the wasp before entering my room, a small quantity of liquid may not have exuded from its wounds, which may have helped the wasp in tracking it. I have no doubt myself that insects have the sense of smell, and probably much more developed than our own. No one, as you remark, who has sugared for moths, or seen the large sphingidæ hovering over the strongest scented flower at night, or employed a caged female moth as a lure to her male admirers, can, I think, doubt this. If so, let them put a saucerful of honey in a corner of a room opening into a garden, throw open the window, and see how soon the bees, wasps, &c., will be attracted to the honey.

There is a tradition in the east that one of the tests by which the Queen of Sheba tried to prove the wisdom of Solomon, was placing on a table before him two bouquets, one of artificial, and the other of natural flowers, and requiring that he should say which were the real and which the artificial, without moving from his throne. Solomon ordered the windows to be thrown open, and in flew the bees, &c., which went at once to the real flowers.

Whether the senses of insects, birds, and what we call the lower creation, are similar to ours in every respect, it is very difficult to say. No doubt a dog, if he could speak, would say a man had not the sense of smell, and would prove that his nose was worse than useless to him. An eagle or hawk would say that men and moles, &c., have only the rudiments of eyes, and so on.

Man, with five very imperfectly developed senses (who can say that there are not twenty senses), is the only animal that is dogmatical, and denies all he cannot understand. The oracle of Delphi said "Socrates was the wisest man in Greece, *because he was the only man who knew he knew nothing*." Yours faithfully,

C. L. W. MERLIN

To Henry Cecil, Esq., Bournemouth.

A NEW CAMERA LUCIDA

THE various kinds of camera lucida hitherto used have always possessed many inconveniences, none of them allowing to be seen upon the paper with sufficient precision, and simultaneously, the image of the object and the point of the pencil. For the purpose

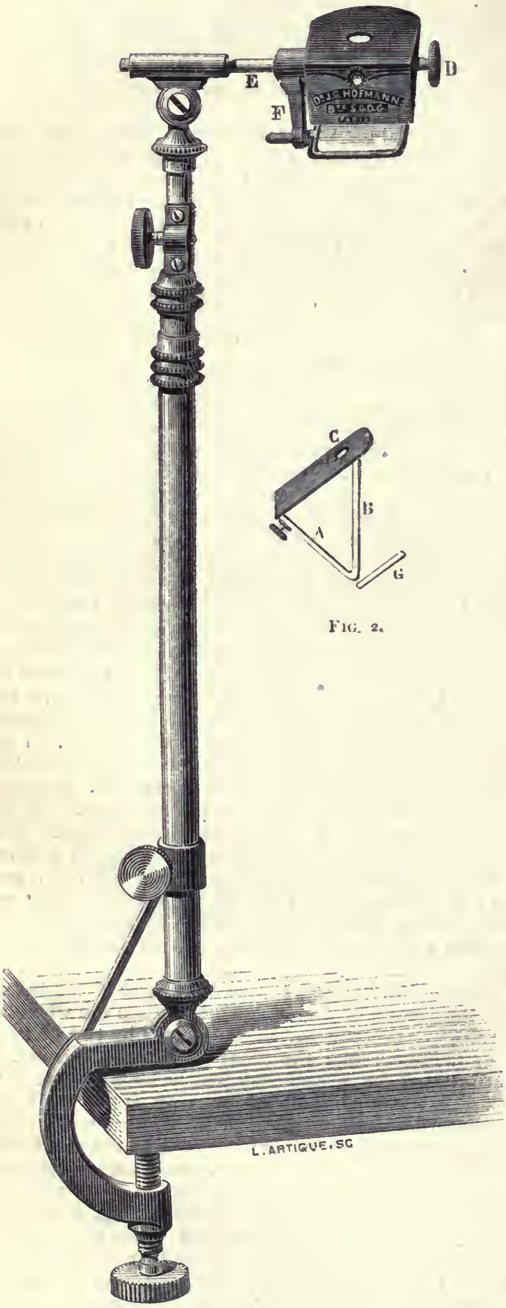

FIG. 2.

FIG. 1.

of remedying this inconvenience, Dr. J. G. Hofmann, of the Rue Bertrand, Paris, has had recourse to an arrangement by which he believes he has obtained the most satisfactory results. The illustration will give some idea of this arrangement.

Fig. 1 represents the general elevation, in half size, of Hofmann's camera lucida. Fig. 2 is a transverse section of the optical part, composed, at A, of a metallised mirror, or other metallic surface, polished and rigorously plane; at B, of a small plane mirror of parallel glass, forming, with the metallised mirror, a fixed angle. The function of the latter is to let pass a part of the luminous rays coming from the object to be drawn, and to show at the same time the point of the pencil alongside the image upon the paper. At G may be placed, in a movable frame, either a plate with parallel surfaces, or lenses of neutral glass of various foci, the principal object of which is to enable a satisfactory drawing to be made of the objects placed inside, when using white paper; for the outside, this glass serves to temper the brightness of the sun.

At C is the eye-hole or opening before which the eye is placed. The knob D serves to place the chamber in a convenient position, which sometimes depends on that of the artist with respect to the object; but generally it is convenient to place the mirror D vertically. With the same pieces of the optical part, with the addition of a concentrating lens, Dr. Hofmann has been able to construct a second model applicable to microscopes, for which, as well as for telescopes, all previous forms of camera have given only very mediocre results.

ANATOMICAL PREPARATIONS FOR MUSEUM AND CLASS PURPOSES

IN a former number of NATURE (vol. xvi. p. 360) I offered some suggestions on museum preparations and arrangement. These I can now supplement by a new method which I have tried with encouraging success.

No museum-curator needs to be reminded of the many defects of the ordinary fluid-preservatives. Evaporation, blanching, spilling, optical distortion, the cost and inconvenient shape of glass vessels—these are among the serious and apparently inevitable advantages of dilute spirit. I have found it possible to get rid of all these difficulties together by mounting dissections and entire animals in glycerine jelly.

The following directions may be followed until experience shall suggest better. Soak gelatine (best quality) in water until it has absorbed as much as it can, melt and add an equal bulk of best German glycerine. Clarify with white of egg, one egg to a pint of mixture, taking care to boil very steadily, without burning. Filter hot through flannel. The jelly should be transparent, and of a pale straw-colour. It should melt at 39° C., and have a specific gravity of 1·186 at 8° C., compared with water at the same temperature.

The jelly may be diluted with water, with glycerine, or with a mixture of the two. I find one part of jelly to one of glycerine and one of water a convenient proportion. The dilute jelly is apt to run fluid on exposure to the air, owing to the growth of moulds. This may be prevented by using a solution of salicylic acid or thymol in water for dilution. These substances cause opalescence in the medium, but a very minute quantity of acetic acid clears it again.

Lay out the dissection on wax, as recommended in my previous letter, but without pins, and fill up with jelly rendered fluid by gentle heat. When the vessel is full, allow the jelly to cool and set, then pour a little more on the top. After this also has set, lay the glass cover (warmed by immersion in hot water) in its place. As the superficial layer of jelly melts, press the cover down. When cold, cement the edges with strips of cloth smeared with coaguline.

The vessel for mounting may be of almost any size and shape. I have tried glass jars, built-up glass cells, ebonite, gutta percha, earthenware, and wood soaked in paraffin. The vessel should be strong and quite air-tight.

It is early as yet to speak of the final result. Some preparations have lasted five months without alteration.

The inert character of glycerine jelly, so well-known to microscopic mounters, justifies confidence in its stability. A large proportion of glycerine may render certain objects too transparent. This tendency may be corrected by changing the proportions as required, or by adding alum. I have found even delicate colours, such as those of squids, readily preserved by the jelly. No effusion of mucus or colouring matter takes place, and an animal may be mounted fresh if care be taken that the jelly penetrates sufficiently into cavities of the body. Previous immersion in alcohol, or other preservatives, does not prevent re-mounting in glycerine jelly. Many of the ordinary reagents used by the histologist may be added to obtain special results. I have not as yet succeeded with large objects, but mountings with as much as a pint of jelly have done well.

The cost of the jelly is not prohibitive, and when the freedom from loss by evaporation, or spoiling by turbidity and discoloration is considered, this mode of preparation will be found cheapest in the end. Harvey and Reynolds, of Leeds, undertake to supply the undilute jelly at a moderate price.

Until experience suggests improvements I have nothing to add. The preparations ought to be kept for years before the new process can be recommended in unqualified terms. I think, nevertheless, that I have already seen enough to warrant the anticipation that mounting in jelly will for certain purposes displace all the fluid methods in use. L. C. MIALL

Leeds Museum

BEES

AN American correspondent writes asking Mr. A. R. Wallace, through NATURE, his opinion as to the genus *Apis*. Are *dorsata, zonata, indica, adansoni, nigro-cincta,* and *florea*, each or all distinct species? or, our correspondent asks, are some of these like *ligustica* and *fasciata*, simply varieties of *mellifica?* Also as to structure and habits of *A. dorsata* and others, which Mr. Wallace has personally seen and handled.

The following reply has been sent us to these queries:—

Mr. Alfred R. Wallace having suggested that I should answer the queries of your American correspondent, I do so at once, having in the year 1865 published in the *Annals and Magazine of Natural History*, a somewhat elaborate paper on the subject on which information is sought for. The species that in my opinion are distinct are *Apis mellifica, A. adansoni, A. dorsata, A. zonata, A. unicolor, A. indica*, and *A. florea*. I do not consider the examination of worker bees only sufficient material to enable any one to form a decisive opinion as to species; the examination of drones, also, I consider indispensable; it is advantageous to see queens, but those which I have seen do not present any very marked peculiarities indicative of specific distinction. I possess males and workers of *A. dorsata, A. indica*, and *A. florea*. That *A. ligustica* and *A. fasciata* are climatal varieties of *A. mellifica* has been apparently proved by the fact of their having in England reverted to the original stock, *A. mellifica;* there is, however, a remarkable fact to be noticed that, notwithstanding the change referred to, they still possess a much greater degree of irascibility than *A. mellifica; A. fasciata* undoubtedly in the greatest degree. I consider *A. zonata* distinct from *A. dorsata*, its nearest ally; it is a larger bee, jet-black, with snow-white bands on the abdomen; I have not seen *A. dorsata* from Celebes, where *A. zonata* was discovered by Mr. Wallace, but he found that species in Sumatra, Flores, Timor, and Gilolo. *A. adansoni*, and *A. nigro-cincta*, will probably prove to be climatal varieties of one species, the latter being a pale form with dark bands. There is no doubt of *A. indica* being a distinct species, all the sexes are known, and there is no other species found in India with which it could be assimilated. Of the specific distinction of *A. florea*, the remarkable structural formation found in the drone, that of a lobe on the metatarsus, is conclusive; it is also much the smallest species known of the genus Apis. *A. unicolor* inhabits Madagascar, Mauritius, and the Island of Rodriguez; a considerable portion of a swarm was obtained from the latter island, an examination of which inclines me to consider the insect much more than a climatal variety of any other species; it remains that the drones and queens should be obtained in order to decide the question; until this can be effected I shall consider *A. unicolor* a good species.

Of the habits of the species of the genus Apis, Mr. Wallace, Sir John Hearsey, Dr. Jerdon, and Mr. Chas. Horne have given some interesting particulars. *A. dorsata* suspends its mass of combs on the branches of trees, quite exposed, having no covering whatever; Sir John Hearsey succeeded in obtaining a swarm which he secured in a box-hive, thus domesticating the species, and obtaining from time to time quantities of delicious honey. Dr. Jerdon gave me combs of *A. indica*, which had taken up its abode in the rafters of an outhouse. Mr. Horne gave me the comb of *A. florea;* it is attached to a twig of some bushy plant. Dr. Welwitsch brought combs of *A. adansoni* from Angola; they were found inside a hollow tree; the cells are considerably smaller than those of any of the honey-bees of Europe. FREDERICK SMITH

British Museum

THE ORION NEBULA

A SHORT time ago we gave an abstract of d'Arrest's "spectroscopical researches." The Danish paper contains also the conclusions at which he arrived after many years contemplation of the nebula in the sword-handle of Orion. The spectrum is now easily visible, with open slit, even without a telescope. Then we see three images of the nebula corresponding to the three lines, whose relative intensity d'Arrest found to be 100, 24, and 71. To see the fourth line is of course very difficult. If the spectrum of the stars is looked at together with that of the nebula, we find the nebular lines continue absolutely unimpaired through the inner trapeze. Consequently it cannot be considered as proved that the stars are in connection with the nebula. It has not, of course, yet been possible to ascertain spectroscopically whether the stars are nearer to us than the nebula, or farther away in space. The question of resolvability has lost a good deal in interest since Huggins showed its gaseous nature. However, d'Arrest would not believe that it had ever been resolved into stars in any of the large telescopes of his day. All the more startling was the Rev. Dr. Robinson's letter (NATURE, vol. xv. p. 292), that he as early as 1848 had resolved this nebula with the Earl of Rosse's telescopes. It would be worth while for Mr. Ellery, who, according to our astronomical column, is investigating the southern nebulæ, to ascertain whether actual resolvability is referred to here, or the circumstance that, as might be expected in so enormous a reflector, a good many small stars become visible by glimpses. Liapounov describes the appearance of Regio Hugeniana as follows: "Ces masses m'avaient présenté à plusieurs occasions des ressemblances frappantes avec des amas d'étoiles. Le caractère stellaire s'est prononcé d'abord dans la masse la plus lumineuse, dont l'apparence me conduisait depuis constamment à l'idée d'une agglomération de petites étoiles condensées." We are hardly right in concluding that the nebula could be resolved in the nine-inch refractor of the Cazan observatory.

The Orion nebula was first pictured together with the four stars of the trapeze by Huyghens, who discovered it in 1656, though Cysat referred to it already in 1618. It was afterwards examined by Derham, Godin, Fouchy, Mairan

and Picard. Legentil compared its outline to that of the open mouth of an animal. Messier was the first who gave a catalogue of the stars seen in the nebula. Schröter, in Lilienthal observed it, 1794-1799. It was this eminent astronomer who discovered that this chaotic mass is not in perfect equilibrium, and several of the changes he pointed out have been verified by modern observers. Sir W. Herschel watched the nebula during thirty-seven years. He believed that changes were taking place in Nebula Mairani. The most important fact connected with the discovery of changes was, that the three conspicuous stars ϵ, ζ, and η (J. Herschel, 1825), in most of these old maps, are represented as inside the bright nebulosity, while they are now seen far from it. D'Arrest showed that no changes have occurred here by aid of a drawing, which Lefebvre published, 1783, in Roziers, "Observations de la Physique." He also remarked the characteristic circumstance that in this figure Sinus Magnus is represented as running right across the trapeze, which, in consequence, is lying altogether outside the nebula. Lefebvre's drawing is, however, executed in the style of those that preceded Messier. It is of uniform brightness and sharp outlines.

Sir J. Herschel appears to have been the first who understood that in order to ascertain changes, it was required to give faithful drawings of all the minute parts of the nebula. His first drawing was executed in 1824, and that was, in 1847, followed by the beautiful figure founded on micrometric measurements made at the Cape, 1834-1837. He attributes hardly any weight to the first drawing, which had been made with freehand, compared with the last one.

Lamont published, 1837, an image of the brightest part of the nebula which Herschel criticised. He found, for instance, Regio Hugeniana more uniform, and marked with certain channels, while Lamont represented it as consisting of rounded masses running into each other. Later authorities agree with Herschel, but it deserves to be remarked that he had not himself, 1824, remarked these channels, nor are they laid down on Cooper's map. It so happens that the refractor in Copenhagen is exactly similar to that in Munich, and in consequence a comparison of the respective drawings made at an interval of thirty-five years could not but be of importance. There is no trace of the sharp outline in the north-west corner, which the Danish drawing shows, and it is so much more likely that here great alterations in brightness have taken place, as all the old drawings, for instance Cooper's, support Lamont, while the later ones in this respect agree among themselves. Amongst the most remarkable differences d'Arrest classed Pons Schröteri in Sinus Magnus. Lamont has of this bridge only the small piece, which, like a promontory, is attached to the north side, while d'Arrest saw the brightest patches about midway. On the above-mentioned old drawing by Cooper, Pons Schröteri is only represented as three small pieces emanating from the north side, while the same is now in the large refractor of the Markree Observatory only noticed as a little spot in the middle of the bay. Such changes were already alluded to by Schröter, and modern diagrams support this hypothesis.

Liapounov's diagram, drawn after most careful micrometric measures,[1] represents the object as seen about 1850. He agrees with Lamont about Regio Hugeniana, and also about the east point, which he found well defined against the far fainter Proboscis Major. He observed Sinus Lamontii, which he surrounded by the bright nebulosity, since called Hemicyclium Liapounovii. The darkness of this Sinus varied considerably, and thus it was explained why it was not noted by Herschel, though indicated on Cooper's map. Liapounov represented Pons Schröteri as emanating from the north side of Sinus Magnus, but he made it end with a bright spot, and his representation is, therefore, the midway between older and later drawings. Few astronomers have conducted similar researches so earnestly and faithfully as the Russian professor, and his merits have not been so highly appreciated as they deserve. It appears to me that this is even the case from the side of his Danish colleague.

Lassell published in 1854 a steel engraving, which was badly executed, the regions round Sinus Magnus in particular. Nebula Mairani was made brightest of all the nebulæ, while it only holds the third or fourth place. All these drawbacks have, however, been removed from the second drawing made in Malta, 1862 and 1863, which is one of the best extant.

The drawing Secchi published in 1868 is not to be trusted, and even the central region is wrongly drawn. D'Arrest had made a similar remark about an earlier figure by Secchi, to which the Papal astronomer answered: "Che la figura litografica pubblicata, benchè esatta in generale, ha alcune inesattezze non trascurabili." The possibility of a similar explanation in the present case was excluded by the remark: "Cosi siamo sicuri che l'incisione rappresenta la nebulosa come vedesi da noi nel nostro strumento."

George Bond's drawing, of about 1860, is in d'Arrest's opinion, more like the nebula than any that has been drawn from a refractor, and the characteristic calmness over the whole has been successfully imitated. He only saw the northern boundary, and the parts about Palus Bondii somewhat different from Bond. The divisions in the south-east corner of the nebula, so prominent in the drawings made of late with gigantic telescopes, do not appear so distinct in d'Arrest's refractor as in Bond's. In Markree it is not possible to trace them at all. On this point Rosse's drawing contains more particulars than any that I have seen.

The most complicated drawing of the nebula was published in 1868, by the present Earl of Rosse. D'Arrest found this drawing to be very accurate. The dark channels in Regio Hugeniana are, however, rather broad, and two large spots north of the bright mass too prominent, the boundaries are generally considered too sharp, and the contrast between the stronger and feebler parties rather strong by those accustomed to other telescopes; but it does not appear that the limits to which nebulosity was traced are much farther than in the refractors of Cambridge, United States, and Copenhagen. The feeble streams of nebulosity which connect the θ with the southern ι nebula have been well studied at Birr Castle, while the faint northern branches were more attended to in Cambridge, United States, where Bond first traced the connection with the c nebula. The connection between θ and ι was known to d'Arrest since autumn, 1865.

On Rosse's drawing the east point of the main part is bent somewhat and does not go smoothly over in Proboscis Major. Thus far this agrees with d'Arrest, but the image at present seen in the Markree refractor is more like Bond's figure. D'Arrest evidently gives the almost straight south-eastern outline of Regio Hugeniana too great concavity. Rosse, d'Arrest, and Holden agree well about the part west of Sinus Gentilii. Hereabout the Roman drawing does not correspond to nature at all. Nor are the diagrams of Liapounov and Cooper in accordance with d'Arrest. Now this might arise from the different quality of their telescopes, but it is not unlikely that some change has taken place here, though d'Arrest does not offer this explanation. But he declares Sinus Lamontii and Hemicyclium Liapounovii to be very changeable. The agreement of the different diagrams of Lacus Lassellii is striking; it was remarked already in 1795, by Schröter, and notwithstanding possible fluctuations in brightness, no alteration in the form has taken

[1] From a discussion of his own and W. Struve's observations, Liapounov concluded that three stars of the trapeze were moving with respect to the fourth, the most southern star. An investigation, on the whole confirmative of this, was read by Prof. Nobile, last year, before the Reale Accademia of Naples.

place during the last eighty years. On the whole this constancy in the form d'Arrest considers the principal result of all our studies of this object. The changes, which have been remarked, seem all reduced to mere variations in intensity, but such small alterations may greatly change the impression we get on looking at certain parts of the nebula.

The nebula has of late been well watched at the United States Naval Observatory. Prof. Holden has been hitherto engaged in making micrometric measurements of prominent parts of the nebula and noting the order of brightness of the various masses. He will even attempt a little photometry with the 26-in. refractor. The stars suspected to be variable by O. Struve, are nightly observed. From a provisory discussion of the observations, Holden alludes to changes of short period, and a preliminary sketch of the central part shows that his discoveries in nebular astronomy are likely to rank with those of Newcomb and Hall in other parts of the science. W. D.

AMERICAN GEOLOGICAL SURVEYS

NORTH-WESTERN WYOMING AND YELLOWSTONE NATIONAL PARK [1]

IN a former number of NATURE (vol. xii. p. 265) some account was given of the various independent surveys in progress among the western territories of the United States. Allusion was then made to the unfortunate want of concert among them which had led to a reduplication of the work, and consequently to a struggle at Washington between the different surveying staffs, one fighting for a continuance of power, another for very existence. By the decision adopted by Congress the Engineer Department retained control only of those surveys which might be required for military purposes, while the geographical, geological, and other surveys, carried on for the purpose of exploring new ground and making its features and productions known were to be taken charge of by the Department of the Interior. Such a limitation ought to be sufficient to prevent any future risk of the same tract of country being surveyed twice by different and independent officers. That it was needed became abundantly evident during the time of the contest which was finally settled by Congress. And the present volume furnishes fresh proof of its necessity.

Early in the year 1873 the Engineer Department organised a surveying party to make a military reconnaissance of the north-west of Wyoming territory lying between the Union Pacific Railroad and the line of the Northern Pacific Railroad in Montana. As this department had all along been in the habit of employing civilian geologists, naturalists, botanists, and other scientific observers, Captain Jones, who took command of the expedition, collected a party of nineteen persons, exclusive of a military escort under four officers. This military character which the engineers have given to their reconnaissances, though, perhaps, hardly avoidable, seems with good reason to have been regarded as irritating to the Indians. During the investigation into the question of reduplication of surveys, it was stated by the geologists of the Department of the Interior that they did not wish any escort of soldiers as they were never molested by the Indians, who would have been suspicious of their movements had soldiers accompanied them. Captain Jones, indeed, refers to a large war-party of Sioux Indians which came into Big Horn Valley shortly after he and his expedition had passed out of it, and he seems to think that he made a lucky escape. But the appearance of so large a body of armed men as he commanded within the lands reserved by treaty to the Indians could hardly fail to awaken their distrust and set them in motion.

[1] Report upon the Reconnaissance of North-Western Wyoming, including Yellowstone National Park, made in the summer of 1873, by W. A. Jones, Capt. U.S. Engineers, with Geological Report by Prof. T. B. Comstock. (Washington: Government Printing Office.)

The country passed over in the route lay across the formidable range of rugged snow-capped mountains which rise round the head-waters of the Yellowstone. By some travellers this lofty barrier had been pronounced to be inaccessible, one picturesque observer declaring that "a bird cannot fly over that without taking a supply of grub along." Once across the watershed the expedition descended upon the basin of the Yellowstone, which had already become famous for its wonderful hot springs, and had been pretty fully described and carefully mapped. Indeed when one remembers how much had already been done in the scientific exploration of North-western Wyoming, one is tempted to ask whether the elaborate preparations made by Capt. Jones were really needed. Nearly a half of the geological part of the Report is occupied with a description and discussion of the geyser phenomena of the National Park—a very interesting and important subject, but one which had already been largely treated of, and which does not appear to be quite in its proper place in the midst of a military reconnaissance. Dr. Hayden, who had done so much to make known the structure and the wonders of that region, is cited in the report, but not in such a way as to suggest any adequate notion of the relative importance of his labours and those of Capt. Jones's expedition. The most important geographical point established by the latter traveller was the existence of an easily traversible pass through the mountains between the head of Wind River and the sources of the Yellowstone. He named it Togwotee Pass, and found that though it reaches an elevation of 9,621 feet above the sea, the slopes leading to it are so gentle that a railway might be led through it at a reasonable cost.

Prof. Comstock, who was attached as geologist to the expedition, contributes a series of geological chapters to the Report. They are well written, and show him to be not only a good observer, but one who endeavours to group what he sees round some leading principles in science. In particular he adopts a systematic method of treatment in preference to the order of observation usually followed in such reports. This plan saves his readers at a distance much time and trouble, besides enabling them to grasp the main outlines of his work far more clearly than would be otherwise possible. He begins by giving a general outline of the physical geography of the region, connecting the area examined by the party with the rest of the Rocky Mountain tracts as far as explored by other observers. Availing himself of the previous labours of Hayden, Clarence King, Whitney, and others, he arranges his narrative of the geological history of the region in stratigraphical order, beginning with the most ancient metamorphic or archæan rocks, and leading his readers through the Silurian, Carboniferous, Triassic, Jurassic, Cretaceous, Tertiary, and Post-tertiary systems. In seven interesting chapters Prof. Comstock discusses the questions in dynamical geology suggested by the work of the expedition. In pointing out the evidences for glacial action in North-western Wyoming, he admits that even the hardest rocks fail to show traces of glacier-striation; that in all his journey he had only seen two or three faint scratches approaching the nature of a glacial mark, but which might have been made quite recently. He found, however, on the Wind River plateau long and high ridges composed of huge granite boulders and immense blocks of Silurian and other rocks, with intervening lakes or ponds, and he no doubt correctly regards these features as glacier-moraines. He finds evidence of enormous erosion in recent geological times, and points out the causes now at work in producing rapid disintegration and removal of rock. Among these he mentions the great altitude of the region allowing of the accumulation of large masses of snow, and of the alternate freezing and thawing of the snow by night and day; the steepness of the slopes favouring rapid erosion, and the character of the rocks powerfully influencing alike the amount of

waste and the nature of the resultant forms of surface. The wind plays a not unimportant part in modifying the scenery partly by transporting vast clouds of sand away from the mountains and forming sand-hills in the plains, partly by felling large quantities of timber which obstruct the flow of surface-water, dam up streams, and render the country for wide distances all but impenetrable. The action of vegetation in preserving the surface of loose soil from disintegration, and in giving rise to mould, turf, and other accumulations is illustrated by examples met with on the journey. The author enters with considerable minuteness into the dynamics of the Yellowstone geyser region. He carefully describes eighteen groups of thermal springs, and distinguishes these somewhat arbitrarily, as he admits, from the geysers or eruptive springs, of which he enumerates twenty-five. In two concluding chapters he gives some account of the archæology of the region and of the manners and customs of the Eastern Shoshone Indians, from jottings made by him in intervals of leisure during the march. The Report is illustrated by forty-nine small sketch-maps of each day's march, two large general maps of the region traversed (one coloured geologically), and numerous sketches and sections. As a record of three months of daily toil in a wild little-known region the volume is creditable to its authors, and as a source of information regarding one of the most interesting regions of North America it will be useful to geological and general readers.

ARCH. GEIKIE

NOTES

THE programme of the fifty-first meeting of the German Naturalists and Physicians (the German equivalent of the British Association) will be held this year at Cassel, from September 18 to 24. This, probably the most thoroughly scientific and efficient of all the Associations, consists of twenty-five sections, ranging from Mathematics and Astronomy to Veterinary Surgery. This year a number of addresses on leading topics by eminent men of science are promised. Among these are the following:—"On the Relation of Darwinism to Social Democracy," by Prof. Oscar Schmidt, of Strassburg; "On Symbiosis, Parasitism, and Allied Phenomena of Life," by Prof. De Bary, of Strassburg; "On the Education of the Physician," by Prof. Fick, of Würzburg; "On the Physician in his Relation to Research and Natural Science," by Prof. Hüter, of Greifswald; "On Harvey's Life and Work," by Dr. Baas, of Worms; "On the Colour-sense and Colour-blindness," by Dr. J. Stilling, of Cassel. Many other attractions are promised, including excursions, social gatherings, and the inevitable winding-up "Abschieds-Commers." The various German railways will afford great privileges to those attending the meeting.

WE have received a circular issued by the local committee of the American Association, which meets at St. Louis on August 21, giving detailed directions as to how to reach the place of meeting from different points. From this circular we learn that the railway companies, proprietors of Pullman and other luxurious cars, various express companies, and the local hotel-keepers, afford unusual facilities to members at greatly reduced rates. The concluding excursion of the meeting is to be to the Rocky Mountain region of Colorado, the details of which have not yet, however, been arranged.

THE thirty-fifth annual congress of the British Archæological Association will be held at Wisbeach, from August 19 to 27, under the presidency of Lord Hardwicke.

WE are sure that all our readers will be pleased to hear that a Civil List Pension of 200*l*. per annum has been granted to Dr. Prescott Joule.

THE Royal Society of Sciences at Upsala have shown their appreciation of Mr. Alex. Buchan's work as a meteorologist by electing him a foreign member of their body.

MR. P. S. ABRAHAM, M.A., B.Sc., of St. Bartholomew's Hospital, who recently catalogued the Nudibranchiate Mollusca at the British Museum, has been engaged to arrange scientifically, and to write a descriptive catalogue of the natural history collections at the Winchester Town Museum.

LAST week we spoke of the generosity of the United States Government in the distribution of the publication of their admirable surveys. We regret to see, from a speech in the House of Representatives by the Hon. O. R. Singleton, that the usefulness of Dr. Hayden's surveys threatens to be seriously crippled from want of funds. The appropriation for this survey in 1867 was only 5,000 dollars, which in 1873 had been raised to 95,000 dollars. In 1876, however, this was reduced by 30,000 dollars, and again, in 1877, by 20,000, leaving the appropriation at only 45,000 dollars. The largest sum is what is actually needed that the survey may be carried on with efficiency, and to reduce it is quite unworthy of a nation so advanced and liberal as the United States, and is really the worst possible economy. The additions which have been made to science by Dr. Hayden's survey have been immense and of the highest importance, and its economic value to the country can be no less great. The mere list of the many admirable publications of the survey is sufficient to prove that the money has been well spent; and we trust the United States Government and Congress will be able to rise above all party feeling, and prove to the world that they have the best interests of the country and the interests of scientific knowledge at heart by restoring the appropriation to at least its old amount. Mr. Singleton truly says not a small item in favour of these surveys is the check they place on mining and land swindles.

WE have received the first number of the *American Journal of Mathematics*, to which we have already referred on more than one occasion. It is a large quarto of 104 pages, the chief editor being Prof. Sylvester. Its contents will bear comparison with those of any similar publication on this side of the water. We can only give a list of the papers in this number: "Note on a Class of Transformations which Surfaces may undergo in Space of more than Three Dimensions," by Prof. Simon Newcomb; "Researches in the Lunar Theory," by G. W. Hill; "The Theorem of Three Moments," by Dr. H. T. Eddy; "Solution of the Irreducible Case," by Guido Weichold, of Zittau, Saxony; "Desiderata and Suggestions," by Prof. Cayley—"No. 1. The Theory of Groups;" "Note on the Theory of Electric Absorption," by H. A. Rowland; a review, by Mr. C. S. Peirce, of Lieut.-Col. Ferrero's "Espozione del Metodo dei Minimi Quadrati;" "On an Application of the New Atomic Theory to the Graphical Representation of the Invariants and Covariants of Binary Quantics," by Prof. Sylvester. The first announcement of Prof. Sylvester's remarkable application of the chemical theory was made in NATURE (vol. xvii. p. 284). The London publishers of the journal are Trübner and Co.

ON the 21st will be opened the new magnetic observatory at Pavlovsk in connection with the Central Physical Observatory of St. Petersburg. The new observatory covers about eight hectares of surface, and the situation is in all respects favourable. The establishment comprises three principal scientific buildings, the main building of stone and surmounted by a tower for meteorological observations; a double-arched structure in stone covered with earth for observations in magnetic variation; and a wooden pavilion, without a particle of iron, for absolute magnetic measurements and for determinations of time. Besides these three buildings devoted to the purely scientific work of the

observatory, there are four wooden houses for lodging the staff, servants, and for other purposes. All these structures are roofed with bituminized paper, and we need scarcely say that the scientific buildings are at a sufficient distance from the other buildings to prevent the scientific observations being affected by their neighbourhood. The Pavlovsk Observatory is furnished with the most improved scientific instruments, and like the Central Physical Observatory of St. Petersburg, is a model establishment of its kind. Every precaution has been taken, both during the building and after its completion, to prevent a trace of iron getting near it. The instruments themselves have been put in their places under the personal superintendence of Dr. Wild, the head of the Central Observatory at St. Petersburg. Provisionally the work of the establishment at Pavlovsk will be specially directed to the observation of the meteorological elements and of terrestrial magnetism. As soon as trustworthy methods have been found for the constant measurements of other elements, such as atmospheric electricity, terrestrial currents, radiation of heat, the optics and chemistry of the sun and sky, these elements will also form the objects of normal observations.

MR. MURRAY has the following books in the press:—"Researches and Adventures among the Lakes and Mountains of Eastern Africa," from the journals of the late Capt. F. Elton, H.B.M.'s Consul in Mozambique; this work will include notes on the suppression of the slave trade, and will be edited, with additions, by the author's companion, H. B. Cotterill; "Sketches of the Natives of Burmah," an account of their manners, customs, and religion, by Capt. C. J. F. S. Forbes, the officiating Deputy Commissioner of British Burmah; the fifth division of Dr. Percy's "Metallurgy," which will treat of silver; and a third revised edition of Mr. E. B. Tylor's "Researches into the Early History of Mankind." Mr. Murray will also publish in autumn the life of another Scottish naturalist, by Dr. Smiles. This newly discovered prodigy, a baker, whose name was Dick, has been dead ten years, and is said to have been an even more remarkable man than Thomas Edward. The principal sphere of his geological and botanical labours was in the region of the Pentland Firth and Dunnet Bay, on the north-west of Scotland.

THE problem of technical education, of which so much has been said of late, has long occupied the attention of thoughtful men in France and Germany. In the former of these countries the question has received much more attention than in the years preceding the war of 1870. In a recent conference at the Trocadéro Palace, M. Corbon, who has laboured in this direction for forty years, urged the introduction of manual employments and of the practical teaching of the skilled industries into the higher schools. He spoke of the good results which had been found to follow the establishment of the municipal School of Apprenticeship in Paris. Although founded only a few years ago, their system of teaching has attained a high degree of development; the mechanical trades being particularly well taught and the pupils of the school being in great demand by masters. Examples of the work of pupils of this excellent institution are shown at the Paris Exhibition in the building known as the "Ville de Paris." Visitors to Paris interested in scientific and technical education should not fail to note the collection of objects there shown. They would also find the school well worthy of a visit. It is situated at No. 60, Boulevard de la Villette.

IT is stated that the Jablochkoff electric lights now so brilliantly employed in the Avenue de l'Opera of Paris are costing 20*l*. per night, but the four-and-thirty lamps that illuminate that street give much more light than is necessary for the purposes of street-lighting. The problem of electric lighting is evidently one in which the scientific workers across the channel are deeply interested. It is stated that no less than eighteen different kinds of regulators for the electric light are exhibited at the Paris exposition; not including the "candle" of M. Paul Jablochkoff.

M. MAUMENÉ recently communicated to the Société de Physique, of Paris, a discovery of some importance in thermochemistry. Concentrated sulphuric acid which has been left for some months undergoes a change of condition of a singular nature. On mixing a liquid such as olive oil, with, say, one-tenth of its weight of fresh concentrated acid, a certain constant rise of temperature is observed, but if acid three months old is used, the rise of temperature so obtained has a value of about 8° C. less. The same results occur even if the acid has been hermetically sealed in glass tubes. With water and other liquids analogous results are found. It is evident that some of the most important data of the thermal effects of chemical action may require revising in the light of this discovery.

THOUGH it is very difficult to obtain any details about their jealously-guarded country, a Japan contemporary gathers that the condition of the Coreans is just now miserable in the extreme. The spring crops of this year, it is said, will utterly fail, and the stock of food in the country is reported to be a mere nothing for the four or five millions of people, who must, if they can, struggle on in the hope of a possible autumnal harvest. The cause of the Corean famines is not known, but it is probable that the primary cause there, as in China, is disafforestation, for, although the forests of pines, oaks, &c., on the sea-board are carefully preserved, a great drain must have thinned the woods by the river-sides. Much or most of the wood used in Peking for building houses, temples, and palaces is said to come from Corea, and from the same source are obtained the vast supplies needed for Tientsin and the cities of the province of Chihli, which lie on the Pei-ho, Peitang-ho, and the Grand Canal. Corea produces various woods of the finest quality, and the cart shafts, dray poles, and axle-trees in Northern China are made out of the tough and strong Corean ash, elm, hornbeam, and other hard timber. We think, however, that our contemporary is in error in stating, without qualification, that "the great wooden masts which support the noble temples and gatehouses of the Imperial city of Peking (all enormous, beautiful, and enduring spars) come from Corea," for there is no doubt that most of the magnificent wooden pillars to be found in the halls of the Ming tombs and the Peking palaces and temples came from the Chaotung department and other parts of the Yünnan province. The timber in question is called by the Chinese *nan-mu*, and is to be seen in the places mentioned at the present day in perfect condition after the lapse of nearly three hundred years. It may not be uninteresting to add that it is not teak, as is often supposed by foreigners, and that the tree is tall, thin, straight-growing, having no bough or twigs on the stem, but suddenly shooting out branches at the top somewhat like a canopy over a maypole, and its bark is of a peculiar ashy grey colour. This is the account given of it by Mr. Consul Davenport in his Report on the trade capabilities of the country traversed by the Yünnan Mission in 1875-76, who also observed in the Manwyne valley, in the Kakhyen hills, and again in Lower Burmah, in places comparatively accessible, many trees bearing so striking a resemblance to the valuable *nan-mu* that the Indian Government have been recently instituting inquiries into the subject with a view to the development of the timber trade in British Burmah.

WE have received the first part of a new "Anatomisch-physiologischen Atlas der Botanik," by Dr. Arnold Dodel-Port, of Zurich, and his wife, published by Schreiber, of Esslingen. The atlas will be published in two forms containing forty-two and sixty plates respectively, to suit different classes of schools. It

is the finest publication of the kind we have seen, and the plates are of such a size that they may be hung up on the wall. The plants and various parts of plants in the part sent us are magnified from 15 to 8,000 times, and are most beautifully and successfully coloured according to nature. Explanatory text accompanies each plate, and as an aid to botanical teaching it would be difficult to imagine anything more useful and attractive; it would be a boon to teachers and students of botany to have the Atlas published in this country.

THE Harvard Library *Bulletin* No. 8, the *Nation* states, announces that a sufficient subscription to Scudder's "Catalogue of Scientific Serials" has been secured, and that the work will be immediately put to press.

THE eleventh annual report of the Peabody Institute of Baltimore shows that the institution is efficiently serving the various scientific, literary, and artistic purposes for which it was established.

LAST Friday, at half-past 8 P.M., a magnificent meteor was seen at Privat, in the Ardèche Department. The meteor broke into several pieces and emitted a magnificent blue light.

THE state of the weather in the principal Algerian towns is posted regularly at the Meteorological Pavilion in the Trocadero, Paris. A special column is devoted to describing the state of the sea, but the writers having the care of translating the telegrams are so ignorant that they have posted a notice for several days telling the Parisians that "the sea was very smooth at Laghouat and Biskra," two Saharan cities!

THE French *Journal Officiel* has published a notice intimating that a school for telegraphy has been established, and that the course of instruction will be opened in October next. Pupils will be admitted after a competition. Preliminary examinations will take place in several cities of France, and the final examination will take place in Paris. A certain number of places is reserved to the pupils of the Polytechnic School, without competition, though it is expected that this privilege will be cancelled by the Chamber of Deputies when deliberating upon the matter next session.

THE inflation of the great Giffard balloon was completed on Sunday evening. Aeronauts are now busy arranging the manœuvres, and it is expected that the preliminary ascents will be made at the end of this week. Next week M. Tissandier will make a communication to the Academy of Sciences on behalf of M. Giffard, who has appointed him general manager. MM. Eugene and Jules Godard and Camille Dartois have been appointed aeronauts. Free ascents will be made twice a week from the Cour des Tuileries. The reappearance of a monster captive balloon will very likely revive an interest in aeronautics. We have heard of many contemplated experiments on a smaller scale. Some Americans have constructed, with light oiled silk, a cylinder six feet in height and twenty feet long, which has been filled with pure hydrogen. This elongated balloon supports an immense sheet in silk, on which advertisements are to be painted and exhibited at fixed rates per hour. The effect is said to be very graceful indeed.

IT is stated, on the authority of the *Agricultural Gazette* of Hanover, that a discovery has recently been made of a new remedy for the prevention of ravages to cabbages by the common caterpillar. A steward of an estate in Hanover having observed that one bed of cabbages was left untouched by caterpillars, whilst others were infested with them, found that the healthy bed had a quantity of dill growing on it, the smell of which, apparently, was obnoxious to the caterpillars. As dill will grow in almost any soil, it is suggested that the experiment might be tried by agriculturists. As indicative of the possibility of there being some truth in this, *The Colonies and India* says:—"We have heard of the common green ("gooseberry") caterpillar being kept off by planting broad beans close to the bushes—and the pyrethrum, a strong smelling weed which is cultivated as a garden border flower—is said to protect vines from the ravages of the *Phylloxera*.

THE phenomenon of supersaturated solutions of salts forms the subject of an elaborate study by M. D. Gernez (*Ann. de l'École normale*, 1878). He finds that besides water a number of other liquids, such as carbon-disulphide, the hydro-carbons, the phenols, and notably the alcohols, afford instances of this peculiarity. A substance which does not yield supersaturated solutions with one solvent never yields them with another, nor can the phenomenon be produced by the addition of substances such as dextrin, tending to increase the viscosity of the solvent. The salts yielding these solutions most easily are sodium carbonate, calcium nitrate, magnesium sulphate, plumbic acetate, and alum. In the case of all five crystallisation ensues only on the introduction of crystals of an isomorphous substance, and the latter lose this property if once heated above a certain temperature, for example, 98° for alum. The author gives a list of 120 substances which possess the property of yielding these solutions.

THE Ethnographic Congress in connection with the Paris Exhibition was opened on Monday. The President, M. Leon de Rosny, delivered a somewhat vague and apparently not over scientific address, in which he defined ethnography as the study of conscious humanity, the discovery of the law of the evolution of humanity in its relation with the general laws of the universe. While anthropology studied individuals or grouped them only according to physical affinities, ethnography recognised groups formed by collective consent and based on compatibilities of temperament and intelligence. It was the fashion, indeed, to decry half-breeds; but the majority, if not the whole, of nations prominent in history had been mixed races, and this mixture was the law of nature, though, under unfavourable conditions, it sometimes proved a failure.

THE report of the Miners' Association of Cornwall and Devon for the year 1877 is, we are glad to say, as satisfactory as usual.

MR. E. SCHÖNE, of Moscow, who is making extended researches on the presence of peroxide of hydrogen in the air, communicates recently the results of his investigations on its presence in the solid and liquid depositions from the atmosphere. He finds that in general the percentage of peroxide of hydrogen increases with the height above the earth's surface at which the condensation of the aqueous vapour takes place. Thus rain always contains more than snow—the rain-clouds moving, as is well known, at a higher elevation than those yielding snow—mists which take their origin near the earth's surface contain comparatively little, and dew and frost show no traces.

THE additions to the Zoological Society's Gardens during the past week include a Beatrix Antelope (*Oryx beatrix*) from Tyef Hedgar, presented by Commander Burke, s.s. *Arcot*, two Crested Porcupines (*Hystrix cristata*), a Banded Ichneumon (*Herpestes fasciatus*) from East Africa, presented by Dr. G. P. Badger; four Paradise Whydah Birds (*Vidua paradisea*), a pin-tailed Whydah Bird (*Vidua principalis*), three Grenadier Weaver Birds (*Euplectes oryx*) from East Africa, presented by Mr. Archibald Brown; a Barn Owl (*Strix flammea*) from Mesopotamia, presented by Commander Wyatt, s.s. *Deccan*; a Hawk's-billed Turtle (*Chelone imbricata*) from the East Indies, presented by Capt. Henderson; a Water Chevrotain (*Hyomoschus aquaticus*), an Electric Silurus (*Malapterurus beninensis*) from West Africa, a Plantain Squirrel (*Sciurus plantani*) from Java, purchased; a Chimpanzee (*Troglodytes niger*) from West Africa, four Vulturine Guinea Fowls (*Numida vulturina*) from East Africa, deposited; a Hairy Tree Porcupine (*Sphingurus villosus*) born in the Gardens.

THE EXPLANATION OF CERTAIN ACOUSTICAL PHENOMENA [1]

MUSICAL sounds have their origin in the vibrations of material systems. In many cases, *e.g.* the pianoforte, the vibrations are free, and are then necessarily of short duration. In other cases, *e.g.* organ pipes and instruments of the violin class, the vibrations are maintained, which can only happen when the vibrating body is in connection with a source of energy capable of compensating the loss caused by friction and generation of aërial waves. The theory of free vibrations is tolerably complete, but the explanations hitherto given of maintained vibrations are generally inadequate, and in most cases altogether illusory.

In consequence of its connection with a source of energy, a vibrating body is subject to certain forces, whose nature and effects are to be estimated. These forces are divisible into two groups. The first group operate upon the periodic time of the vibration, *i.e.* upon the pitch of the resulting note, and their effect may be in either direction. The second group of forces do not alter the pitch, but either encourage or discourage the vibration. In the first case only can the vibration be maintained; so that for the explanation of any maintained vibration, it is necessary to examine the character of the second group of forces sufficiently to discover whether their effect is favourable or unfavourable. In illustration of these remarks, the simple case of a common pendulum was considered. The effect of a small periodic horizontal impulse is in general both to alter the periodic time and the amplitude of vibration. If the impulse (supposed to be always in the same direction) acts when the pendulum passes through its lowest position, the force belongs to the second group. It leaves the periodic time unaltered, and encourages or discourages the vibration according as the direction of the pendulum's motion is the same or the opposite of that of the impulse. If, on the other hand, the impulse acts when the pendulum is at one or other of the limits of its swing, the effect is solely on the periodic time, and the vibration is neither encouraged nor discouraged. In order to encourage, *i.e.* practically in order to maintain a vibration, it is necessary that the forces should not depend solely upon the position of the vibrating body. Thus, in the case of the pendulum, if a small impulse in a given direction acts upon it every time that it passes through its lowest position, the vibration is not maintained, the advantage gained as the pendulum makes a passage in the same direction as that in which the impulse acts being exactly neutralised on the return passage, when the motion is in the opposite direction.

As an example of the application of these principles, the maintenance of an electric tuning-fork was discussed. If the magnetic forces depended only upon the position of the fork, the vibration could not be maintained. It appears, therefore, that the explanations usually given do not touch the real point at all. The fact that the vibrations are maintained is a proof that the forces do not depend solely upon the position of the fork. The causes of deviation are two: the self-induction of the electric currents, and the adhesion of the mercury to the wire whose motion makes and breaks the contact. On both accounts the magnetic forces are more powerful in the latter than in the earlier part of the contact, although the position of the fork is the same; and it is on this *difference* that the possibility of maintenance depends. Of course the arrangement must be such that the retardation of force *encourages* the vibration, and the arrangement which in fact encourages the vibration would have had the opposite effect, if the nature of electric currents had been such that they were more powerful during the earlier than during the later stages of a contact.

In order to bring the subject within the limits of a lecture, one class of maintained vibrations was selected for discussion, that, namely, of which *heat* is the motive power. The best understood example of this kind of maintenance is that afforded by Trevelyan's bars, or rockers. A heated brass or copper bar, so shaped as to rock readily from one point of support to another, is laid upon a cold block of lead. The communication of heat through the point of support expands the lead lying immediately below in such a manner that the rocker receives a small impulse. During the interruption of the contact the communicated heat has time to disperse itself in some degree into the mass of lead, and it is not difficult to see that the impulse is of a kind to encourage the motion. But the most interesting vibrations of this class are those in which the vibrating body consists of a mass of air more or less completely confined.

If heat be periodically communicated to, and abstracted from, a mass of air vibrating (for example) in a cylinder bounded by a piston, the effect produced will depend upon the phase of the vibration at which the transfer of heat takes place. If heat be given to the air at the moment of greatest condensation, or taken from it at the moment of greatest rarefaction, the vibration is encouraged. On the other hand, if heat be given at the moment of greatest rarefaction, or abstracted at the moment of greatest condensation, the vibration is discouraged. The latter effect takes place of itself, when the rapidity of alternation is neither very great nor very small, in consequence of radiation; for when air is condensed it becomes hotter, and communicates heat to surrounding bodies. The two extreme cases are exceptional, though for different reasons. In the first, which corresponds to the suppositions of Laplace's theory of the propagation of sound, there is not sufficient time for a sensible transfer to be effected. In the second the temperature remains nearly constant, and the loss of heat occurs during the *process* of condensation, and not when the condensation is effected. This case corresponds to Newton's theory of the velocity of sound. When the transfer of heat takes place at the moments of greatest condensation or of greatest rarefaction, the pitch is not affected.

If the air be at its normal density at the moment when the transfer of heat takes place, the vibration is neither encouraged nor discouraged, but the pitch is altered. Thus the pitch is *raised*, if heat be communicated a quarter period *before* the phase of greatest condensation, and the pitch is *lowered* if the heat be communicated a quarter period *after* the phase of greatest condensation.

In general both kinds of effects are produced by a periodic transfer of heat. The pitch is altered, and the vibrations are either encouraged or discouraged. But there is no effect of the second kind if the air concerned be at a loop, *i.e.*, a place where the density does not vary, nor if the communication of heat be the same at any stage of rarefaction, as in the corresponding stage of condensation.

The first example of aërial vibrations maintained by heat was found in a phenomenon which has often been observed by glass-blowers, and was made the subject of a systematic investigation by Dr. Sondhauss. When a bulb about three quarters of an inch in diameter is blown at the end of a somewhat narrow tube, 5 or 6 inches in length, a sound is sometimes heard proceeding from the heated glass. It was proved by Sondhauss that a vibration of the glass itself is no essential part of the phenomenon, and the same observer was very successful in discovering the connection between the *pitch* of the note and the dimensions of the apparatus. But no explanation (worthy of the name) of the production of sound has been given.

For the sake of simplicity, a simple tube, hot at the closed end and getting gradually cooler towards the open end, was first considered. At a quarter of a period *before* the phase of greatest condensation (which occurs almost simultaneously at all parts of the column) the air is moving inwards, *i.e.* towards the closed end, and therefore is passing from colder to hotter parts of the tube; but the heat received at this moment (of normal density) has no effect either in encouraging or discouraging the vibration. The same would be true of the entire operation of the heat, if the adjustment of temperature were instantaneous, so that there was never any sensible difference between the temperatures of the air and of the neighbouring parts of the tube. But in fact the adjustment of temperature takes *time*, and thus the temperature of the air deviates from that of the neighbouring parts of the tube, inclining towards the temperature of that part of the tube *from* which the air has just come. From this it follows that at the phase of greatest condensation heat is received by the air, and at the phase of greatest rarefaction is given up from it, and thus there is a tendency to maintain the vibrations. It must not be forgotten, however, that apart from transfer of heat altogether, the condensed air is hotter than the rarefied air, and that in order that the whole effect of heat may be on the side of encouragement, it is necessary that, previous to condensation, the air should pass not merely towards a hotter part of the tube, but towards a part of the tube which is hotter than the air will be when it arrives there. On this account a great range of temperature is necessary for the maintenance of vibration, and even with a great range the influence of the transfer of heat is necessarily unfavourable at the closed end, where the motion is very small. This is probably the reason

[1] Friday Evening Lecture, by Lord Rayleigh, M.A., F.R.S., March 15, at the Royal Institution of Great Britain.

of the advantage of a bulb. It is obvious that if the *open* end of the tube were heated, the effect of the transfer of heat would be even more unfavourable than in the case of a temperature uniform throughout.

The sounds emitted by a jet of hydrogen, burning in an open tube, were noticed soon after the discovery of the gas, and have been the subject of several elaborate inquiries. The fact that the notes are substantially the same as those which may be elicited from the tube in other ways, *e.g.*, by blowing, was announced by Chladni. Faraday proved that other gases were competent to take the place of hydrogen, though not without disadvantage. But it is to Sondhauss that we owe the most detailed examination of the circumstances under which the sound is produced. His experiments prove the importance of the part taken by the column of gas in the tube which supplies the jet. For example, sound cannot be obtained with a supply tube which is plugged with cotton in the neighbourhood of the jet, although no difference can be detected by the eye between the flame thus obtained and others which are competent to excite sound. When the supply tube is unobstructed, the sounds obtainable are limited as to pitch, often dividing themselves into detached groups. In the intervals between the groups no coaxing will induce a maintained sound, and it may be added that, for a part of the interval at any rate, the influence of the flame is inimical, so that a vibration started by a blow is damped more rapidly than if the jet were not ignited.

Partly in consequence of the peculiar behaviour of flames, and partly for other reasons, the thorough explanation of these phenomena is a matter of some difficulty; but there can be no doubt that they fall under the head of vibrations maintained by heat, the heat being communicated periodically to the mass of air confined in the sounding tube at a place where, in the course of a vibration, the pressure varies. Although some authors have shown an inclination to lay stress upon the effects of the current of air passing through the tube, the sounds can readily be produced, not only when there is no through draught, but even when the flame is so situated that there is no sensible periodic motion of the air in its neighbourhood. In the course of the lecture a globe intended for burning phosphorus in oxygen gas was used as a resonator, and, when excited by a hydrogen flame well removed from the neck, gave a pure tone of about ninety-five vibrations per second.

In consequence of the variable pressure within the resonator, the issue of gas, and therefore the equivalent of heat, varies during the vibration. The question is under what circumstances the variation is of the kind necessary for the maintenance of the vibration. If we were to suppose, as we might at first be inclined to do, that the issue of gas is greatest when the pressure in the resonator is least, and that the phase of greatest development of heat coincides with that of the greatest issue of gas, we should have the condition of things the most unfavourable of all to the persistence of the vibration. It is not difficult, however, to see that both suppositions are incorrect. In the supply tube (supposed to be unplugged, and of not too small bore) stationary, or approximately stationary, vibrations are excited, whose phase is either the same or the opposite of that of the vibration in the resonator. If the length of the supply tube from the burner to the open end in the gas-generating flask be less than a quarter of the wave length in hydrogen of the actual vibration, the greatest issue of gas *precedes* by a quarter period the phase of greatest condensation; so that if the development of heat is *retarded* somewhat in comparison with the issue of gas, a state of things exists *favourable* to the maintenance of the sound. Some such retardation is inevitable, because a jet of inflammable gas can burn only at the outside, but in many cases a still more potent cause may be found in the fact that during the retreat of the gas in the supply tube small quantities of air may enter from the interior of the resonator, whose expulsion must be effected before the inflammable gas can again begin to escape.

If the length of the supply tube amounts to exactly one quarter of the wave length, the stationary vibration within it will be of such a character that a node is formed at the burner, the variable part of the pressure just inside the burner being the same as in the interior of the resonator. Under these circumstances there is nothing to make the flow of gas, or the development of heat, variable, and therefore the vibration cannot be maintained. This particular case is free from some of the difficulties which attach themselves to the general problem, and the conclusion is in accordance with Sondhauss' observations.

When the supply tube is somewhat longer than a quarter of the wave, the motion of the gas is materially different from that first described. Instead of preceding, the greatest outward flow of gas *follows* at a quarter period interval the phase of greatest condensation, and therefore if the development of heat be somewhat retarded, the whole effect is unfavourable. This state of things continues to prevail, as the supply tube is lengthened, until the length of half a wave is reached, after which the motion again changes sign, so as to restore the possibility of maintenance. Although the size of the flame and its position in the tube (or neck of resonator) are not without influence, this sketch of the theory is sufficient to explain the fact, formulated by Dr. Sondhauss, that the principal element in the question is the length of the supply tube.

The next example of the production of sound by heat, shown in the lecture, was a very interesting phenomenon discovered by Rijke. When a piece of fine metallic gauze, stretching across the lower part of a tube, open at both ends and held vertically, is heated by a gas flame placed under it, a sound of considerable power, and lasting for several seconds, is observed almost immediately *after* the removal of the flame. Differing in this respect from the case of sonorous flames, the generation of sound was found by Rijke to be closely connected with the formation of a through draught, which impinges upon the heated gauze. In this form of the experiment the heat is soon abstracted, and then the sound ceases; but by keeping the gauze hot by the current from a powerful galvanic battery, Rijke was able to obtain the prolongation of the sound for an indefinite period. In any case from the point of view of the lecture the sound is to be regarded as a *maintained* sound.

In accordance with the general views already explained, we have to examine the character of the variable communication of heat from the gauze to the air. So far as the communication is affected directly by variations of pressure or density the influence is unfavourable, inasmuch as the air will receive less heat from the gauze when its own temperature is raised by condensation. The maintenance depends upon the variable transfer of heat due to the varying *motions* of the air through the gauze, this motion being compounded of a uniform motion upwards with a motion, alternately upwards and downwards, due to the vibration. In the lower half of the tube these motions conspire a quarter period *before* the phase of greatest condensation, and oppose one another a quarter period after that phase. The rate of transfer of heat will depend mainly upon the temperature of the air in contact with the gauze being greatest when that temperature is lowest. Perhaps the easiest way to trace the mode of action is to begin with the case of a simple vibration without a steady current. Under these circumstances the whole of the air which comes in contact with the metal, in the course of a complete period, becomes heated; and after this state of things is established there is comparatively little further transfer of heat. The effect of superposing a small steady upwards current is now easily recognised. At the limit of the inwards motion, *i.e.* at the phase of greatest condensation, a small quantity of air comes into contact with the metal, which has not done so before, and is accordingly cool; and the heat communicated to this quantity of air acts in the most favourable manner for the maintenance of the vibration.

A quite different result ensues if the gauze be placed in the *upper* half of the tube. In this case the fresh air will come into the field at the moment of greatest rarefaction, when the communication of heat has an unfavourable instead of a favourable effect. The principal note of the tube therefore cannot be sounded.

A complementary phenomenon discovered by Bosscha and Riess may be explained upon the same principles. If a current of *hot* air impinge upon *cold* gauze, sound is produced; but in order to obtain the principal note of the tube the gauze must be in the upper, and not as before in the lower, half of the tube. An experiment due to Riess was shown in which the sound is maintained indefinitely. The upper part of a brass tube is kept cool by water contained in a tin vessel, through the bottom of which the tube passes. In this way the gauze remains comparatively cool, although exposed to the heat of a gas flame situated an inch or two below it. The experiment sometimes succeeds better when the draught is checked by a plate of wood placed somewhat closely over the top of the tube.

Both in Rijke's and Riess' experiments the variable transfer of heat depends upon the motion of vibration, while the effect of the transfer depends upon the variation of pressure. The gauze must therefore be placed where both effects are sensible,

i.e. neither near a node nor near a loop. About a quarter of the length of the tube, from the lower or upper end, as the case may be, appears to be the most favourable position.

RAYLEIGH

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

AMONG the bequests of the late Mr. Henry Brown, J.P., formerly of Bradford, is a sum of 5,000*l*. to the Yorkshire College, Leeds, for the purpose of founding and maintaining scholarships.

THE New York *Nation* states that Dr. A. S. Packard, jun., has been appointed Professor of Natural History at Brown University. His departure from Salem, Mass., the *Nation* states, following on Prof. Morse's and Prof. Putnam's is a serious loss to that scientific centre, and implies an inadequate endowment of the Peabody Academy of Sciences.

THE first conferment of degrees by the Johns Hopkins University took place on June 13. Four candidates were admitted to the degrees of Ph.D. and M.A.

THE following figures, which have been published quite recently at Algiers, will give an idea of the state of public instruction in that colony. Superior instruction is represented only by a preparatory school of medicine in Algiers. It is contemplated to establish in that city a university of letters, science, law, and medicine; but no step has yet been taken to realise the scheme. There are colleges, or lycées at Algiers, Oran, Constantine, Bone, Philippeville, Blidah, Mostaganem, and one or two other places, and two clerical institutions, one at Blidah, and the other at Algiers. The number of pupils of these establishments is 3,142 in a population of 344,849 of European extraction. Primary instruction is given in 803 schools, frequented by 66,343. A few natives follow the course of instruction in European or secondary schools. Most of them are pupils in the Algiers lycée, which has no less than 980 pupils, and is considered one of the best under the authority of the French government, even in France. Great efforts have been made to organise French-Arab schools for natives, but with not much success. Within the last few years thirteen French-Arab schools have been opened in the Sahara and Kabylè, which have now 1,481 pupils. The aggregate number of young Arabs, receiving education from the French government, is only 1,573 boys, and 173 girls out of a population of 2,500,000. A normal school has been established at Mustapha, near Algiers, and numbers from thirty to forty pupils.

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 4, 1878.—This number commences with a paper by M. Schering on friction currents as exemplified in the rubber of a (cylinder) electrical machine. For production of such currents it is unimportant whether the cylinder be connected to earth or not; and the occurrence of *opposite* electricities at the two ends of the rubber is also not essential. The electricity on the hinder margin of the rubber is derived from the insulator (cylinder); for it agrees in sign with that of the latter, and nearly always disappears when the insulator is connected to earth. The friction causes a less quantity of negative electricity to exist on the hinder margin of the rubber than on the forward margin; the quantity of electricity steadily varies from the hinder to the forward margin.—M. Fröhlich investigates the intensity of diffracted light in relation to that of the incident light. His experimental results closely correspond to those of theory. With small angles the entire incident energy of motion appears again after diffraction as light-motion.—Fresnel's theory of diffraction phenomena is treated at some length by M. Voigt.—Studying certain hydrodynamic problems in relation to the theory of ocean currents, M. Zöppritz concludes, *inter alia*, that the influence of friction has, in one direction, been underrated, in another overrated; the former, because it has not been supposed to extend deep enough, the latter, because in regard to propagation of variable current-motions too much has been ascribed to it. He calculates that with a mean ocean depth of 4,000 m. the trade winds in their present extent and strength would have to blow 100,000 years ere the present state of motion of the equatorial current could be supposed approximately stationary. The damping influence of continents and islands would somewhat diminish the number.—M. Antolik communicates further observations on the gliding of electric sparks, obtaining new evidence for the fact that a greater tension is required for discharge of positive than for that of negative electricity, and that the one kind passes more rapidly and further than the other.—A formula determining the rotation of the plane of polarisation in quartz for all colours as function of the temperature, is given by M. Sohncke, who also finds that the rotation in chlorate of soda increases with rising temperature in a greater degree than in quartz.—An improved tangent galvanometer for lecture purposes (based on the principle of the Gauss-Weber mirror-magnetometer), a modification of the mercury air-pump, and a method of more accurate measurement of thickness by means of the spherometer, are among the remaining subjects here dealt with.

No. 5.—M. Kohlrausch here describes a "total reflectometer," or instrument by means of which the total reflection in solid bodies is utilised for determination of refraction. (The instrument can also be adapted for liquids.) A liquid is employed which refracts more strongly than the body examined (generally sulphide of carbon). The author gives his numerical results in a table.—A paper on the theory of double refraction, by M. Lommel, furnishes, with two previous papers, the outlines of a new theory of light (he says it might be called the "friction theory"), in which the phenomena in their connection are explained by the reciprocal action of the ether and the particles of bodies.—M. von Waha calls attention to some interesting movements obtained in badly-conducting liquids (as olive oil or petroleum), when *placed, e.g.*, on a horizontal metallic plate, connected electrically with one pole of a Holtz machine, while a point connected with the other pole is held above the liquid.—The phenomena of resonance in hollow spaces are investigated mathematically and experimentally by M. Wand, and an improved anemometer, capable of measuring the mean velocity of air-currents of constant direction between wide limits, forms the subject of a paper by M. Recknagel.

Actes de la Société Helvétique des Sciences Naturelles (C. R. 1876–77) contain an account of the sixtieth meeting of the Society, held at Bex on August 20–22, 1877, together with notes of the sectional meetings, and the following more elaborate memoirs:—On the adaptation of copepod crustaceans to parasitism, by Prof. K. Vogt.—On the fecundation and first development of the ovum, by H. Fol.—On the railway over the Simplon, by Herr Lommel.—Historical account of the mines and salt-works of Bex, by Ch. Grenier.—On the retrogradation of the shadow on the sun dial, by E. Guillemin.—Note on the study of thunderstorms accompanied by hailstorms and electric phenomena, by D. Colladon.—On the geology of the neighbourhood of Bex, by E. Renevier.—On some geological formations in the Bernese Alps, by S. Chavannes.—On the nummulites of the Western Alps, by Ph. de la Harpe.—On the origin and the repartition of the Turbellaria of the deep fauna of the Lake of Geneva, by G. du Plessis.—On the formation of feathers in the gold-hair penguin and *Megapodius*, by Th. Studer.—On the blood corpuscles of *Mermis aquatilis*, Duj., by E. Bugnion.—On a new Amphipode (*Gammarus rhipidiophorus*), by O. I. Catta.—On the doubtful species in the flora of Switzerland, by L. Leresche.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, June 19.—"On the Reversal of the Lines of Metallic Vapours," by G. D. Liveing, M.A., Professor of Chemistry, and J. Dewar, M.A., F.R.S., Jacksonian Professor, University of Cambridge. No. III.

In our last communication to the Royal Society we described certain absorption lines, which we had observed to be produced by the vapour of magnesium in the presence of hydrogen, and certain other lines which were observed when potassium, and others when sodium, was present, in addition to magnesium and hydrogen. These lines correspond to no known emission lines of those elements; but, inasmuch as they appeared to be regularly produced by the mixtures described, and not otherwise, we could only ascribe their origin to the mixtures as distinct from the separate elements. It became a question of interest, then, whether we could find the conditions under which the same mixtures would give luminous spectra, consisting of the lines which we had seen reversed. On observing sparks from an induction coil taken between magnesium points in an atmosphere of hydrogen, we soon found that a bright line regularly appeared, with a wave-

length about 5,210, in the same position as one of the most conspicuous of the dark lines we had observed to be produced by vapour of magnesium with hydrogen in our iron tubes. This line is best seen, *i.e.*, is most steady, when no Leyden jar is used, and the rheotome (the coil we used has an ordinary self-acting one) is screwed back, so that it will but just work. It may, however, be seen when the coil is in its ordinary state, and when a small Leyden jar is interposed; but it disappears (except in flashes) when a larger Leyden jar is used, if the hydrogen be at the atmospheric pressure. This line does not usually extend across the whole interval between the electrodes, and is sometimes only seen near the negative electrode. Its presence seems to depend on the temperature, as it is not seen continuously when a large Leyden jar is employed, until the pressure of the hydrogen and its resistance is very much reduced. When well-dried nitrogen or carbonic oxide is substituted for hydrogen, this line disappears entirely; but if any hydrogen or traces of moisture be present it comes out when the pressure is much reduced. In such cases the hydrogen lines C and F are always visible as well. Sometimes several fine lines appear on the more refrangible side of this line, between it and the *b* group, which give it the appearance of being a narrow band, shaded on that side. We have used various samples of magnesium as electrodes, and they all give the same results. We have also used hydrogen, prepared and purified in different ways: hydrogen prepared by the action of zinc on dilute sulphuric acid, purified by an acid solution of bichromate or permanganate, and by potash, and dried by sulphuric acid; electrolytic hydrogen; hydrogen from dry formiate of soda and soda lime; hydrogen occluded by sodium and expelled by heat; and hydrogen occluded by palladium and expelled by heat. In the last two cases the whole apparatus was connected by fusion, and a Sprengel pump, also connected by fusion, employed to remove the air. In all cases the phenomena were the same.

In addition to the above-mentioned line, we observed that there is also produced a series of fine lines, commencing close to the most refrangible line of the *b* group, and extending with gradually diminishing intensity towards the blue. These lines are so fine and close to one another, that in a small spectroscope they appear like a broad shaded band. We have little doubt that the dark absorption line, with wave-length about 5,140, shading towards the blue, which we previously observed in our iron tubes, and described in our last communication, was a reversal of part of these lines, though the latter extend much further towards the blue than we had observed the absorption to extend. In fact, the bright lines extend somewhat more than half the distance between *b* and F, from forty-five to fifty being visible, and placed at nearly equal distances from each other. They also commence close to the *b* group, *i.e.*, with a wave-length nearly 5,164, but the first two or three lines at that end are not so bright as those which immediately succeed them. The light giving these lines does not extend to more than a short distance from the electrodes, and is generally most conspicuous at the negative electrode. There is a difficulty in consequence of the flickering character of the discharge in getting any accurate measures of them, though they are bright enough, especially at the less refrangible end, to be easily seen. The comparative faintness of the light from the iron tubes appears to us almost sufficient to account for our not having seen the reversed lines so completely as the bright ones; nevertheless, it is quite in accordance with what we in other cases observed, to suppose that some of these lines may be more easily reversed at the temperature of the iron tubes than others.

Zoological Society, June 18.—Arthur Grote, vice-president, in the chair.—The Secretary read extracts from a letter addressed to him by Mr. E. L. Layard, containing remarks on two species of New Caledonian birds.—A second communication from Mr. Layard stated that there was an example of the recently-described woolly cheetah (*Felis lanea*) in the South African Museum at Cape Town.—Mr. Edward R. Alston read a paper on the squirrels of the Neotropical region, in which he recognised twelve out of fifty-nine described species, and redescribed two, *Sciurus rufo-niger*, Pucheran, and *S. pusillus*, Geoffroy, which had been recently overlooked.—Mr. Sclater exhibited and made remarks on a third collection of birds from Duke of York Island, New Britain, and New Ireland, which he had received from the Rev. George Brown, C.M.Z.S. Amongst them was an example of a new fruit-pigeon, proposed to be called *Carpophaga melanochroa*.—A communication was read from Dr. M. Watson, containing a description of the male generative organs of *Chlamydophorus truncatus* and *Dasypus sexcinctus*.—A communication was read from Prof. Garrod on certain points in the anatomy of Levaillant's darter (*Plotus levaillanti*).—A communication was read from Messrs. Garrod and Turner on the gravid uterus and placenta of *Hyomoschus aquaticus*.—A communication was read from Mr. F. Moore containing the descriptions of New Asiatic butterflies of the family Hesperiidæ.—A second communication from Mr. Moore gave a list of the lepidopterous insects collected by the late Mr. R. Swinhoe, in the Island of Hainan.—A communication was read from the Marquis of Tweeddale, F.R.S., being the tenth of his contributions to the ornithology of the Philippines. The present paper gave an account of the collection made by Mr. A. H. Everett in the Island of Bohol. The collection contained representatives of forty-seven species. Although all of these were previously known, seven of them had not been before recorded as being inhabitants of the Philippines.—Dr. O. Finsch, C.M.Z.S., read the description of a new species of starling from Lake Marka-kul, in the Chinese High Altai, which he proposed to name *Sturnus poltaratzskyi*, after Gen. Poltaratzsky, Governor of Semipalatinsk.—A communication was read from Mr. H. W. Bates containing the description of new species of coleopterous insects (*Geodephaga* and *Longicornia*) taken by the late Dr. Stoliczka during the Forsyth Expedition to Kashgar in 1873–1874.—A communication was read from Dr. G. Hartlaub, in which he gave the description of a new species of *Notauges* (*N. hildebrandti*) of Cabanis, M., discovered by Mr. Hildebrandt at Ikanga in Ukamba, Eastern Africa.—A communication was read from Lieut.-Col. R. H. Beddome, C.M.Z.S., giving the description of a new batrachian from Southern India belonging to the family *Phryniscidæ*, which he proposed to call *Melanobatrachus indicus*.—Sir V. Brooke, Bart., exhibited and made remarks on a fine head of the male *Gazella granti*, originally described from sketches made by Capt. Speke during Speke and Grant's expedition. The present specimen had been shot by Mr. Arkwright about eighty miles from Ugogo in Eastern Africa.—A communication was read from Prof. v. V. Barboza du Bocage, F.M.Z.S., containing a list of the antelopes observed in Angola.—A communication was read from Mr. Carl Bock, in which he gave the description of two new species of shells from China and Japan.—A communication was read from Mr. Edgar A. Smith, containing the description of five new shells from the Island of Formosa and the Persian Gulf, with notes upon some known species.—Messrs. Godman and Salvin read the descriptions of some apparently new species of butterflies from New Ireland and New Britain, received from the Rev. G. Brown.—Mr. O. Salvin read the twelfth of a series of reports on the collection of birds made during the voyage of H.M.S. *Challenger*. The present paper contained an account of the Procellariidæ, collected during the expedition. Eighty specimens had been obtained belonging to twenty-two species.—Mr. Sclater read some supplementary notes on the curassows now or lately living in the Society's gardens.—Mr. J. Wood-Mason read a paper on the structure and development of the trachea in the Indian painted snipe (*Rhynchæa bengalensis*).

Physical Society, June 22.—Prof. G. C. Foster, vice-president, and afterwards Prof. W. G. Adams, president, in the chair.—The following candidate was elected a Member of the Society: Mr. F. W. Grierson.—Prof. W. G. Adams exhibited a new form of polariscope suitable for projecting on to a screen the figures formed by any crystal, and for measuring the angle between the optic axes. Parallel light from the electric lamp, after traversing a Nicol of about two-inch aperture, is rendered divergent by a set of lenses. The crystal under examination is placed in a recess formed by removing a slice from the middle of a spherical lens which is capable of motion in any direction about its centre, while any movement in the vertical plane passing through the axis of the instrument can be measured by a scale and Vernier; and if, by such a motion, the point on the screen representing the position of one axis, when the two are in the vertical plane, be transferred to that indicating the position initially occupied by the other axis, we have at once a measure of the optic angle of the crystal, for the rotation of two plano-spherical lenses forming an exact sphere has no effect on the direction of the beam.—Mr. Walter Baily read a paper on the effect of starch, salicene, unannealed glass, &c., on polarised light. In his experiments light was passed through a Nicol's prism, then through a quarter undulation plate, and then through a body having an optical structure symmetrical round

an axis in the direction of the ray, such as any of the above-named substances. The axes of the quarter undulation plate being taken as axes of reference, ρ being the angle between the plane of polarisation and one of these axes, σ half the difference of retardation at a given point between the part of the light resolved in a plane through the axis of the body and the part resolved perpendicular to that plane, ϕ being the angle between an axis of the $\frac{1}{4}$-undulation plate and the perpendicular on the axis of the body from the given point (which perpendicular is taken as the initial line in the equation to the ellipse defining the light at such point) and r, θ, being the co-ordinates of this ellipse, the writer finds the equation to the ellipse to be

$$1 + A\cos\theta + B\sin 2\theta = r^{-2}\left\{1 - (A^2 + B^2)\right\}$$
$$\text{where } A = -\cos 2\rho \cos 2\phi$$
$$\text{and } B = \sin 2\rho \sin 2\sigma + \cos 2\rho \cos 2\sigma \sin 2\phi.$$

From this equation diagrams have been drawn to exhibit the condition of the light at every point for different positions of the polariser. For the simple case of salicene or starch, in which the difference of retardation is the same, or nearly so, for all distances from the axis of the body, the diagram consists of a ring of ellipses of various eccentricities and inclinations, each ellipse showing the condition of the light along the radius on which it lies. For the general case in which the difference of retardation is a function of the distance from the axis of the body the diagram consists of two series of curves, one series being "isomorphal" curves or curves along which the eccentricity of the ellipse is constant, and the other series being "isoclinal," or curves along which the inclination of the axis major of the ellipse to the perpendicular in the axis of the body is constant. The general equation to the isomorphal lines is $A^2 + B^2 = \text{constant}$; and to the isoclinal lines is $\frac{A}{B} = \text{constant}$. These two series of curves completely define the form and position of the ellipse of polarisation at every point and render it easy to determine what appearances will be presented on passing the light through an analysing prism in any given position. The results obtained were illustrated by some experiment.—Prof. W. C. Unwin made a communication on the flow from orifices at different temperatures. A paper recently appeared in *The Franklin Journal of Science*, by Mr. Isherwood, giving results of experiments on this subject, and according to him the volume discharged from a given orifice is increased by about 12 per cent. on raising the temperature from 60° to 212°. It is difficult to accept this result, because the friction is known to diminish the discharge by an amount much less than 12 per cent., and no other cause than a decrease of friction can be assigned to account for Mr. Isherwood's results. In the author's experiments the increase of discharge at 190° above that at 60° was only 4 per cent., with conoidal orifices in the form of the vena contracta; with thin edged orifices the variation of discharge was still less. He is disposed to think that the great increase of discharge in Mr. Isherwood's experiments was due to diminution of friction in a rather small pipe leading to the orifices, and would not occur with any other arrangement. —Mr. Graham then read a paper on complementary colours. He stated that the three primaries are green, red, and blue, and not yellow, red, and blue; that yellow is a binary compound of green and red; and that yellow and blue when mixed form white. He remarked that after looking at a green disc the eye evokes another colour, but this is not seen unless certain conditions are fulfilled; thus the undulations must be arrested by a gray surface: this was proved by an experiment in which a green disc carrying a concentric ring half white and half black was caused to rotate, when a medium gray was produced and this at once arrested and made visible pink the complement of the green. Several other complementaries were shown by the same means. Mr. Graham next showed how the grays can be formed by cancelling either reflected or transmitted rays of white light. The first of these cases is illustrated by white paper painted over with a wash of Indian ink, and the second by the well-known Berlin tiles, in which light and shade are obtained by giving varying thickness to the ware. He showed that this last effect may be imitated by piling strips of paper to varying heights, and he has succeeded in photographing geometrical figures so formed. Lastly the author explained a method of arresting and showing the complementaries more satisfactorily than he considers has hitherto been done. Six thicknesses of white paper are gummed together and cut into a ring, a ring of the same size and shape being also cut from a disc of coloured paper, and the white ring is let in to fill its place. On observing such a disc by white transmitted light the complement is seen through the ring.—Prof. S. P. Thompson exhibited a series of magnetic figures illustrating electro-dynamic relations. The lines of magnetic force around a wire carrying a magnetic current can be shown by passing a wire through a glass plate, strewing iron filings around, and tapping the plate gently. The filings may be fixed in their places, if the plate has previously been gummed and dried, by softening the gum with steam. Such a prepared plate may be used to project the figures of the magnetic curves in the lantern. Two parallel like currents attract, their curves forming a figure illustrative of the action; or they repel if travelling in opposite directions, the repulsion also being evident from the form of the curves. It was shown by a series of such lantern-slides that a very large number of electro-dynamic relations can be illustrated by curves produced in this manner. Figures were thrown upon the screen illustrating the law of oblique currents, the attraction of a magnet into or its repulsion out of a circuit, the deflection of a magnetic needle by a current, and the mutual tendency of a current and magnetic pole to rotate. A very curious figure was produced by a current running through a magnet longitudinally. A transverse section of the lines of force at a pole gave neither the radial lines of the magnet nor the circular lines of the current, but a series of spirals. It was argued that Faraday's conception of the lines of force tending to shorten themselves supplied the means of interpreting the physical effects indicated by the lines of force in the various figures.—The Secretary read a paper by Mr. C. H. Hinton, on the co-ordination of space. If a cubical space be divided into twenty-seven numbered cubes, and each of these be again subdivided in the same way, and so on, the position of any point within the initial cube can be expressed by a reference to the numbers of the several cubes in which it is placed, and the more this series of numbers is extended, the more accurately is its position defined; and, further, if we consider an expression of the form $\ldots\ldots rqponm.lkjih\ldots\ldots$ where each letter stands for any number from 1 to 27, and if m, before the dot, indicates the unit space, it will be evident that by such an expression the position of any point in space can be indicated with any degree of accuracy; each letter representing a space twenty-seven times as great as that which immediately succeeds it; or, in place of 27, any other number offering special facilities for any given purpose may be employed. The author then gives some account of the manner in which the system can be utilised for classifying chemical phenomena and in arranging plants, &c.—An adaptation of the telephone and microphone for communicating vibrations to the phoneidoscope, by Mr. Tisley, was then shown. The metal disc carrying the soap film is fixed just above the telephone plate, and, this being in circuit with a microphone and battery, any vibration imparted to the microphone at once sets the soap film in action, the characteristic figures being at once obtained.—Mr. A. Haddon exhibited a modified form of microphone which he has arranged with a view to make the same instrument available for receiving sounds of any given intensity. Its main peculiarity consists in having a thin strip of elastic attached to the middle of the pointed graphite. By varying the tension of this elastic, the sensitiveness of the instrument can be accurately regulated.—The meeting of the Society was then adjourned to November.

Chemical Society, June 20.—Dr. Gladstone, president, in the chair.—The following papers were read:—Contributions to the history of the naphthalene series, No. 2, β naphthaquinone, by Dr. Stenhouse and Mr. Groves. By the action of nitric acid sp. gr. 1·2 on this substance, mononitroy-β-naphthaquinone was obtained in red crystals. By the action of dilute sulphuric acid a dark-coloured compound was obtained, which, on reduction, yielded white acicular crystals, and on oxidation orange-coloured prisms. The new quinone has the formula $C_{20}H_{10}O_4$; the authors purpose to call it dinaphthyldiquinone. It is very stable.—On pyrotritartaric and carbopyrotritaric acids, by Mr. G. Harrow. By saponifying diacetosuccinic ether with dilute sulphuric acid, the author succeeded in preparing these two acids; the author has obtained sodium and silver salts, and discusses their constitution.—Laboratory notes, by Dr. Armstrong.—On the action of alkaline hyprobromite on ammonium salts, urea, and oxamide, Prof. W. Foster. The author gives a *résumé* of the present state of our knowledge as to the action of hypobromite on ammonium salts and urea, with some results of his

own; he then investigates the action of hypobromite on oxamide—74·87 per cent. of its total nitrogen is given off—and endeavours to ascertain the precise condition of the suppressed nitrogen.—Action of the halogens at high temperatures on metallic oxides, by Messrs. C. F. Cross and S. Suguira. With lead oxides oxyiodides are formed, and with the oxides and carbonates of the alkaline earth metals in the presence of oxygen periodates are produced.—On manganese tetrachloride, by Mr. W. W. Fisher. The author has studied the action of strong hydrochloric acid on the black and red oxides of manganese; brown liquids are formed containing a highly chlorinated manganese compound, probably the tetrachloride, which is readily resolved into manganous chloride and free chlorine.—On salts of nitrous oxide, by Mr. A. E. Menke. The sodium salt was obtained by fusing nitrate of soda with iron filings; its properties and reactions were studied. Diver's silver salt was prepared, and its composition confirmed.—Notes on madder colouring matters, by Messrs. E. Schunck and H. Roemer. The authors have prepared some quantity of munjistin and examined its properties, also its reactions with acetic anhydride, bromine, potash, and nitric acid. In all respects munjistin resembles purpuroxanthic acid.—On the occlusion of hydrogen by copper, by Mr. G. S. Johnson. The discrepancy between the results obtained by previous experimenters is explained (1) by the fact that hydrogenised copper retains nearly all its hydrogen in vacuo at a red heat. (2) That the same metal occludes varying quantities of hydrogen. The amount occluded is in most cases sufficient to introduce a serious error in organic analysis. At a red heat copper oxide occludes carbonic acid.—On the *rôle* played by carbon in reducing the sulphates of the alkalies, by Mr. J. Maclear. At a high temperature with excess of carbon, sodium sulphide and carbonic oxide are formed. At a dull red heat sodium carbonate and carbonic acid are produced in addition.—On the action of ethylchlorcarbonate on some oxygenated haloid compounds of the fatty series, by Mr. O'Neil F. Kelly. The compounds employed were allyl alcoholdibromide glycerindichlorhydrin and epichlorhydrin.—The Society adjourned over the recess.

PARIS

Academy of Sciences, July 8.—M. Fizeau in the chair.—The following among other papers were read:—Action of heat on aldol, by M. Wurtz. He obtains, beside crotonic aldehyde, a little ordinary aldehyde, and, in certain circumstances, a new polymer of the aldehyde, which he describes.—On malignant pustule in fowls, by MM. Pasteur, Joubert, and Chamberland. Fowls when cooled contract it easily, and they may then be completely cured by reheating.—Influence of atmospheric electricity on the nutrition of plants, by M. Grandeau. His mode of experiment was to place two plants of the same species (tobacco, maize, wheat) under the same conditions as to soil, aëration, isolation, &c., but the one withdrawn from the action of atmospheric electricity by means of a Faraday's cage. The plants thus withdrawn elaborated, in equal times, 50 to 60 per cent. less of living matters than the others. Plants of small elevation above the ground are also affected by atmospheric electricity. The centesimal amount of proteic matter formed appears not to depend sensibly on this action; it is proportional to the yield. The proportion of ash is higher in plants removed from the electricity; and the proportion of water is less.—On the curves of solubility of salicylic and benzoic acids, by M. Bourgoin. Taking the temperatures for abscissæ, and the quantities dissolved for ordinates, the solubility of salicylic acid in water is represented by a parabolic curve, whose convexity is towards the axis of temperatures.—On the diffusion of fire-damp in mines, by M. Coquillion. The experiments show that it diffuses very slowly from above, but rapidly upwards.—On a disease of malignant pustule form, caused by a new aerobic vibrion, by M. Toussaint. He found this vibrion in a rabbit inoculated from the blood of a horse which had died rapidly with symptoms of malignant pustule.—On *Avenardia Priei*, a giant Nemertian of the west coast of France, by M. Giard. In the state of rest it measures 1 m. to 1·20 m. in length (in extension twice or thrice as long), the width being 2 to 3 ctm. It is found in hundreds in an old canal from salt marshes at Pouliguen, now transformed into a reservoir, where the sea-water is renewed each tide.—Observations and experiments on the migrations of *Filaria rytipleurites*, a parasite of cockroaches and rats, by M. Galet. The eggs produced by the parasite in the alimentary canal of the rat are thrown out with fecal matters, and swallowed by the cockroach. The embryos, when hatched, penetrate the walls of the alimentary canal of the latter, and are encysted in fatty matter, where they await the cockroach being devoured by the rat. In the rat they now complete their cycle.—Experimental researches on the variations of volume of the cranium, and on the applications of the graphic method to solution of various anthropological problems, by M. Le Bon. A superior race contains more of voluminous crania than an inferior. Among 100 modern Parisian heads there are about eleven with a cranium of 1,700 to 1,900 cubic centimetres; in the same number of negro heads not one will be found of such size. The weight of 100 masculine Parisian brains of the present varies between 1,000 and 1,700 grammes, the volume between 1,300 and 1,900 cubic centimetres. The difference between the largest and smallest brains among modern Parisians is three times that observed in the negro, and it is greater than in the Parisians' ancestors of 600 years ago. Stature has only a very slight influence on the volume of the brain. With equal stature woman has a much less heavy brain than man. Rising in the scale of civilisation, the difference in weight of brain (and so volume of cranium) between man and woman is found constantly increasing; thus the average difference of crania of the present Parisian men and women is nearly double that between the crania of the ancient Egyptian men and women. Persons having the same circumference of crania may have differences in volume of over 200 cubic centimetres; but operating on series, 1 centimetre increase of circumference corresponds to an increase of about 100 cubic centimetres in volume. Certain relations are found to exist between circumference of cranium and head, and volume and weight of brain. The cranium is always unequally developed on the two sides, without apparent relation to race or intelligence.—Automatic imitation of mountain chains on a globe according to the theory of upheaval, by M. Chancourtois. This is by the method of a caoutchouc balloon covered with wax, then allowed to contract.—Determination of the orbit of the planet 103, Hera, by M. Leveau.—On the development of the cephalo-thoracic portion of the embryo of vertebrates, by M. Cadiat.

CONTENTS

ERRATA.—Vol. xviii. p. 294, 2nd column, line 22 from top, read for "insolvents" "resolvents;" line 31, for "2m" read "2^m." In last week's "Paris," parenthesis near beginning, for "distillation (which discoloured the fatty acids)" read "distillation (which had been resorted to to purify the fatty acids)."

THURSDAY, JULY 25, 1878

BOTANY IN AMERICA

Synoptical Flora of North America. By Asa Gray, LL.D., Fisher Professor of Natural History (Botany) in Harvard University. Vol. ii. Part 1. (New York, 1878.)

Bibliographical Index to North American Botany, with a Chronological Arrangement of the Synonymy. By Sereno Watson. Part 1, Polypetalæ. (Washington, 1878.)

As with the British nation, so with the American, the rapid extension of its territorial boundaries, and absorption of outlying regions abounding in new and interesting forms of life, has determined to a great extent the direction and progress of the natural history sciences which it cultivates.

The first requisite of the explorer who brings back with him collections illustrative of the new or little-known countries he has visited is to know what these are; and the emigrant and colonist who follows the explorer makes the further demand upon the naturalist of the means of ascertaining the names and relationships of the useful, ornamental, noxious, or otherwise remarkable plants of his new home.

Hence the more rapid strides of classificatory and descriptive botany in England and America than in any other countries, the multiplicity of botanical appendices to narratives of voyages, travels, surveys, and explorations; and those libraries of local and general floras which have contributed so largely to our knowledge of the vegetable world. In this respect, namely, the accession of new domains, America and England have no rival but Russia, and in her case the newly-acquired or explored territories have in many cases, from the scantiness of their floras, yielded comparatively little of botanical interest. France, indeed, during the last decade of the past and first of the present centuries, displayed remarkable activity in this direction, stimulated thereto by the genius and activity of Richard, De Candolle, St. Hilaire, and many other botanists, and by the accumulation of collections brought by her naval expeditions and geographical explorations; but latterly she has left the field to the Anglo-Saxon; and her publications relating to the botany of her later voyages are too often ambitious failures, *ouvrages de luxe;* abandoned and left incomplete after the first few parts have dazzled the scientific world by their size and beautifully executed plates; whilst of her latest and most splendid territorial acquisition, Algeria, we must go to the work of an Englishman (Munby) for even a catalogue of its botanical riches.

America, on the other hand has gone about her work of this kind in an eminently practical fashion. Most of her local floras, and they are very numerous, are exceedingly well done, and complete up to their date of publication, whilst the botanical collections made during her almost innumerable topographical, geological, boundary, and railroad surveys have been published with a completeness and accuracy that leave little to be desired; and these hence form most valuable contributions not only to systematic but to geographical botany.

Of the contributors to this branch of botanical literature in America none is entitled to take rank with Prof. Asa Gray, of Harvard, Massachusetts, whether in respect of the amount of labour undertaken, or the treatment of it; and there is certainly no living botanist whose work has better stood the test of time and subsequent scrutiny, or who has turned his materials to better account in dealing with problems of classification and geographical distribution.

One circumstance alone has stood in the way of the recognition of the merits of this class of work, which is the fragmentary character of most of it, and the fact that so much of it has appeared as appendices and supplements to ponderous volumes descriptive of territorial and other surveys, which have necessarily a limited circulation, and whose titles are unfamiliar to scientific inquirers.

It has long been felt that there was but one way of satisfactorily dealing with the mass of materials of this nature that had been accumulating in the United States for now thirty-five years, and this was the resumption by the surviving author of Torrey and Gray's "Flora of North America," which was begun in 1838, and of which the last part, embracing the Compositæ, was published in 1843. Happily the surviving author has not been allowed to lose sight of the fact, that to him alone would botanists look with confidence for its satisfactory completion, and he has consequently been in the habit of so working up the materials confided to him for publication from the numerous expeditions alluded to and from private sources, that these should be directly available for the final effort to complete the American flora.

In commencing this, two courses were open to Dr. Gray: to re-edit, with additions, the antiquated volumes already published and continue onwards, or to begin where the old work ended, and re-edit afterwards the previously published ones. Dr. Gray has chosen the latter course, and, we doubt not, wisely; it leaves the lighter task for the future. It also more quickly meets the necessary wants of botanists, for the first volumes are, to a very important extent, supplemented by Sereno Watson's "Bibliographical Index to North American Botany," which gives references to all the genera and species added to the American flora since 1843, as well to those published up to that time.

In various other respects, also, the model of the old flora of North America has been advantageously departed from; a new title, of "Synoptical Flora of North America," has been adopted; the pages are larger and the type smaller (though still beautifully clear); synoptical tables of the genera are introduced under each order; and the synonomy and references have been greatly reduced, these being supplied by Watson's above-mentioned bibliography.

The work embraces all the regions of America belonging to the United States and Great Britain, thus excluding Greenland, the flora of which is more European than American. The part now published contains 400 pages, and embraces thirty-two Gamopetalous orders (from Goodeniaceæ to the end of that division of Dicotyledons) according to the sequence of Bentham and Hooker's "Genera Plantarum," the limitation of orders in which work is closely followed. The orders include 321 genera and

1,663 species, according to a statement in the Bulletin of the Torrey Botanical Club of New York (May, 1878), which contains a justly appreciative notice of the work. The preface states that the whole will be completed in two volumes of 1,200 pages each, which, if the forthcoming parts contain as many species as that now before us, would imply that the known phænogamic floras of the area embraced consists of about 10,000 species, a rather larger number than is included in Nyman's "Sylloge Floræ Europeæ," published in 1855, which contains 9,738.

If this latter number represents even approximately the extent of the European Flora, it shows that Europe contains, in proportion to its area and latitude, more plants than temperate North America: for its area (3,600,000 square miles) but little exceeds that of North America, exclusive of the vast British possessions, whilst the United States extends almost into the tropics and contains many subtropical plants. This superior botanical richness of Europe is no doubt due to the great diversity of the floras of its three southern peninsulas, Spain, Italy, and Greece, and to the number of species in its central mountains; as also to the prevalence of annuals, in which Europe far outnumbers any other continent. On the other hand, Dr. Gray's views of the limitation of species are no doubt large, compared with that adopted by Dr. Nyman.

Before concluding this notice of Dr. Gray's work, we may notice the identification of the North American *Solanum Fendleri*, Gray, with the potato (*S. tuberosum*) as var. *boreale*, thus giving this esculent a range from Chili and Buenos Ayres to the United States.

Mr. Watson's "Bibliographical Index to North American Botany" is not a mere compilation, as its title would make it appear, but a first-rate contribution to botanical science; the authorities cited being in all possible cases verified by a reference to the works themselves, and often by a critical study of the specimens by a botanist of scrupulous exactness, who is also well acquainted with the North American Flora, as collaborator with Asa Gray in the herbarium at Harvard. The first part, now published, includes the Polypetalous Dicotyledons, thus covering the ground of the first volume of Torrey and Gray's "Flora of North America," published in 1838–40. Next to Gray's Synoptical Flora this is the greatest boon to systematists that has appeared in North America for many a year, and it is further a necessary adjunct to the Synoptical Flora, containing as it does a mass of citations of descriptions and plates, of which that work is thus relieved.

It is further very interesting as showing the additions made to North American Botany since the publication of Torrey and Gray's above-mentioned first volume. Taking ten of the most considerable American orders of Polypetalæ, we find that in 1840 these included 262 genera and 1,267 species, to which have been added in the thirty-seven years that have elapsed since that period, only 12 genera, but 756 species. In so far as this affords the means of forming a rough estimate, it shows that the discoveries during the period in question, and which are almost confined to the southern and western States, have added about one-third to the previously known North American flora. These additions affect the different orders very variously, as might be expected; thus, whilst the increments to some, as *Ranunculaceæ* (20) and *Caryophylleæ* (16) are small, and of others moderate, as *Onagrariæ* (24), *Rosaceæ* (28), and *Saxifrageæ* (10), those of *Umbelliferæ* (45) are large; the orders *Cruciferæ* (95) and *Onagrariæ* (47) have been nearly doubled, *Leguminosæ* (360) more than doubled; and to *Cacti*, of which but nine species were known at the first period, 111 have since been added!

In two comparatively unimportant matters of convenience the author has departed from usage, and, we think, without good cause; the genera and species are not numbered either in Gray's or Watson's work, on what grounds we cannot imagine. To have to run up the numbers of the large genera (as Astragalus), for the purpose of comparing or contrasting the items of the American flora with those of others, involves a grievous loss of time to the botanist, whilst for the arrangement of herbaria, and ready reference in it to these standard books, the numbering would have been very useful. The other departure is the alphabetical arrangement of the genera under the orders in the "Bibliography," which, in the case of genera absorbed, necessitates a reference to the index.

If a few copies, with the matter printed on one side of the page, could have been obtained by botanists, it would have been a great boon. In such a case the pages of the "Bibliography" might have been intercalated with those of Gray's "Synoptical Flora;" and each species, with its references, might have been cut out and attached to the herbarium specimens of the species.

It remains to wish these able and industrious authors successfully through the works they have so well begun.

J. D. HOOKER

THE HYDROIDS OF THE GULF STREAM

Report on the Hydroida collected during the Exploration of the Gulf Stream by L. F. de Pourtalès. By G. J. Allman, M.D., F.R.S., President of the Linnean Society. (Cambridge, U.S., 1877.)

THIS report forms No. 2, vol. ii. of the quarto memoirs of the Museum of Comparative Zoology at Harvard College, and has been published by permission of the Superintendent of the United States Coast Survey, and is illustrated by thirty-four plates. It forms one of the most important contributions to the natural history of the hydroids that have appeared of late years, and it describes a very large number of most interesting and new forms. One of the sub-orders of the hydroida is well characterised by having the hydroids quite unprotected—not covered by any external protective receptacle. In this sub-order (Gymnoblastea) but nine species were found in Pourtalès' collection. Although they are all referable to known genera, yet all of them are new. The great bulk of the collection belonged, however, to another sub-order, in which the hydroids are provided with external protective receptacles (hydrotheca), and which is more or less familiar to us as containing the Campanularian and Sertularian forms. Of this sub-order (Calyptoblastea) some fifty-six species are described, and among the Sertularinæ no less than seven new genera are described, with forty-two new species out of a total of forty-three. Among the Campanularinæ two

new genera are described, with twelve new species out of a total of thirteen. In addition to these new species there were but seven others which, so far as their identification was possible, were already known as European forms. The collection had been preserved in spirits and was for the most part in excellent preservation. It would seem obvious that the region from which this collection had been obtained, and which includes an area between the Florida Reef on the north and west and Cuba the Salt Key and Bahama Banks on the south and east, is characterised by a very distinct hydroid fauna, and must form part of a special province in the geographical distribution of the Hydroida, though of course further researches may greatly extend the area of the new forms. The greatest depths at which any species had been dredged was 470 fathoms. The collection was rich in the plume-like hydroids (Plumulariadæ). In some genera of this beautiful family of hydroids the ultimate generative zooids which give origin to either the germ or the sperm cells (gonophores) are developed within a horny covering (gonangium), groups of which are often to be found inclosed in most curious basket-like receptacles (corbula). Such basket-like receptacles are well seen in Aglaophenia, and in a new species described as *A. bispinosa*, they attain a very large size and form most beautiful objects. In this genus the twigs of the cradle are much altered pinnæ which are pressed into a protective service. In one of Dr. Allman's new genera nearly allied to Aglaophenia (Cladocarpus) the groups of gonangia are not inclosed in corbulæ, but are borne on the sides or at the base of special protective branches which are not altered pinnæ but appendages to them. They certainly seem to act the part of corbulæ, and to form very effective organs of defence to the gonangia—though they do not present so effectual a covering as in Aglaophenia. In one magnificent species (*Cladocarpus paradisea*) the stem of which attains a height of fourteen inches, these phylactogonia, as Dr. Allman calls them, are in the form of pinnately-branched offshoots. In another species (*Cladocarpus dolichotheca*) the stem for nearly the whole of its course carries a longitudinal series of tubular receptacles which contain sarcode in which thread-cells are found. These nematophores, which are situated at short and equal intervals from one another, give to this part of the hydroid colony a very close resemblance to certain forms of graptolites. Elsewhere Dr. Allman has called attention to the close affinity that appears to exist between the so-called denticles of the graptolites and the nematophores in these Plumularian hydroids; and, as we know, that these bodies in the hydroids are not only filled with protoplasm, and that this is capable of developing pseudopodia after the manner of some rhizopods, this might seem to point to a relationship between the graptolites and the rhizopods through some ancestral form in which the affinities looked on the one side to the hydroids and on the other to the rhizopods, the graptolites having stopped short of the progress which the hydroids were enabled to make.

The beautiful plates illustrating this memoir have been executed by the faithful pencil of Mr. Hollick, though the details of structure have been drawn by the skilled and practised hand of the author. E. P. W.

OUR BOOK SHELF

Automatic Arithmetic: a New System for Multiplication and Division without Mental Labour and without the Use of Logarithms. By John Sawyer, Public Accountant. (London: George Bell and Sons, 1878.)

THIS is an ingenious work, and would have suited the "fantastical" Armado ("I am ill at reckoning; it fitteth the spirit of a tapster"). By the aid of 1759 figures only the user of it is able to multiply any two numbers each not exceeding 999,999,999, and also to divide one number by another, neither exceeding the same limits.

Its advantage over logarithms, in the cases to which it applies, is that the results are accurate instead of approximate.

The principle of construction is very simple: take ten pages; at the top of each write the nine digits in succession (for facility in working, the numbers are printed red and black alternately); cut each page into nine horizontal sections, and at the end of each strip write the same number (viz., for the fifth page the constant number will be 4), then on each strip will be printed

04 08 12 16 20 . . . 36

the printing being so arranged that each strip shall have the numbers of the previous strip printed one place further to the right. From this description it will, we think, be readily seen how to apply the tables to multiplication. To take a very simple example (any other example coming within the limits we have specified can be worked with almost equal facility), multiply 374 by 7.

Take the larger of the two numbers; turn back all the top row slips above 3, then all the second row slips above 7, then all the third row slips above 4, then carry the eye down the vertical column corresponding to the number, and we see (in this case in black figures)—

```
21
 49
  28
```

whence, adding, the result is seen to be 2618.

Each additional figure in the multiplier gives a result similarly obtained, and the answer is got by no mental operation more difficult than simple addition. A mere child who can add numbers together can thus perform mechanically (or automatically) difficult exercises in multiplication. Division is similarly reduced to subtraction. Whether much saving of time and labour is effected is a question we leave to practical men. We showed the work to a class of boys, and they were much interested in watching the process, the principle of which was readily understood by them.

Numbers can thus be easily raised to powers, but the method does not serve for the extraction of roots. We need hardly state that the tables are protected by letters patent.

A Handbook of the Plants of Tasmania. By the Rev. W. W. Spicer, M A., &c. (Hobart Town: J. Walch and Sons, 1878.)

THIS little book of 160 pages contains a great deal more valuable matter than would at first sight appear. The author justifies the production of his book from the fact that previously existing works treating of Tasmanian plants are though "works of extraordinary merit, costly and ponderous," in proof of which he points to the labours of Hooker, Mueller, and Bentham, all of whose works are undeniably of very great value, but if for no other reason than their bulk, quite unfitted to be the companion of a botanical ramble. The book before us is intended for this purpose, being convenient in size, and as the author tells us in his preface, "moderate in cost." With regard to the plan of the book, the author's own description will make it more clear than any words of our own. He says,

"the descriptions are arranged on the branched or binary system, first established by the French naturalist Lamarc. Under this system, a series of salient characteristics is laid before the reader in pairs, the numbers of each pair being as nearly as possible opposed in their terms, and each giving rise to a new pair in like manner contradictory. The choice of these contradictions being left to the reader, he selects the number which applies most nearly to his specimen, and then passes on to the next pair. It is evident that, sooner or later, the several series of characters must be exhausted, and the name of the plant arrived at." The method of using this system is so fully explained further on, that, by following the author, no one can possibly fail to understand it and to be able to identify any plant by its aid. It is, in short, an exhaustive system by which the plant we may be examining is, so to speak, run into a corner and so fixed in its proper place. Thus we have a pocket flora of the colony in which not only the scientific, but, in most cases, also the common or colonial names are given. A short glossary of botanical terms, illustrated by figures, is placed at the beginning of the book, but this includes only such words as it was found absolutely necessary to use in the book. The aim of the author in assisting to popularise a knowledge of Tasmanian plants amongst the colonists will, no doubt, be furthered by the appearance of this little volume. A more careful revision of the proof-sheets, however, would have repaid for the extra time so spent. We think, also, that the adoption of some recognised system of spelling the natural orders would have had its advantages. Thus, we find Ranunculeæ instead of Ranunculaceæ, Lobeleæ instead of Lobeliaceæ, while, on the other hand, Papaveraceæ, Scrophulariaceæ, Lauraceæ, and others, occur as we have written them.

The coloured frontispiece of the Waratah (*Telopea truncata*) is, to say the least, a poor attempt at plant-figuring, both the drawing and colouring being equally bad.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Natural History Collections

I SEE by *Galignani*, the only newspaper that reaches this high elevation, that a bill has just been introduced into Parliament by Mr. Walpole, and read a second time, to enable the Trustees of the British Museum to move the natural history collections into the new building at South Kensington. Not having before me a copy of the Bill, I cannot say whether it contains any clauses to alter the present mode of government of the natural history collections, but if such be not the case, and it is proposed to leave the new institution at South Kensington under the domination of the Trustees of the British Museum, I can assure Mr. Walpole and his friends that they will cause bitter disappointment to the naturalists of the country by such a course of action. We have always looked forward to the epoch of the removal of the national collections of natural history to the new site as the only opportunity ever likely to arise of making a reform in their government. That a Board of Trustees consisting of the principal Officers of State and great nobles of this country could be abolished was, of course, impossible, but it was hoped that the great men of Bloomsbury would not care to extend their authority to South Kensington. It will not be forgotten that the Royal Commissioners on Science, who went into this question in full detail, came exactly to this conclusion, and recommended that the new museum, when constituted, should be placed under a director immediately responsible to one of the ministers. And there can be no doubt that this should be done, and that the Act which authorises the removal of the collections should give them their new constitution. Our two best scientific institutions in this country—Greenwich Observatory and Kew Gardens—are governed after this fashion, and could never have attained their present standard of excellence under the rule of fifty irresponsible trustees.

Let me briefly point out the evils of the present system of government of the British Museum as regards the natural history collections. The "principal librarian" is secretary to the trustees and sole executive officer. His policy is, naturally enough, to get all he can for his books, and to keep the expenditure on the natural history branches as low as possible. One glance at the estimates annually proposed for the various departments in the British Museum will be sufficient to show how well this policy is carried out. It may be that the trustees will ask to appoint a new secretary and executive officer for the new building at South Kensington, and that the estimates for the two institutions will be kept separate. I trust that such may be the case, as it will partially mitigate the evils of which I complain. But I much fear that the principal librarian will resist giving up any part of his present authority, and that the tendency to starve the natural history and pamper the library will remain as heretofore. I earnestly hope, therefore, that Mr. Walpole's bill will not pass into law unless it contain clauses to ensure a cessation of the disadvantages of the present system of government. It would be better far that it should not pass at all this session. Even the fabric of the new building will not be complete until next spring, and there is much to be done in the way of internal arrangements and fittings before the time comes to remove the collections. Why, therefore, should a bill of this importance be introduced and hurried through Parliament at the fag-end of the present session? It must be naturally supposed that the only object is to elude criticism and to keep the rights and privileges of the fifty trustees as far as possible inviolate.

The Genesis of Cyclones

IT is to be gathered from Mr. Barham's communication on cyclones and anti-cyclones in NATURE, vol. xviii. p. 249, that he is probably unacquainted with either Prof. Dove's partial explanation of the effect of the earth's rotation on the winds, published nearly fifty years ago, or Prof. Ferrel's more recent and comprehensive memoirs on the same subject; not to speak of Mohn and Guldberg's elaborate discussion of the mechanics of cyclonic and anticyclonic movements in their "Études sur les Mouvements de l'Atmosphère," published within the last two years.

It is not, however, to point out the fact that Mr. Barham's idea has been anticipated by these, and indeed many other writers, that I address you; but rather to show that the theory of parallel currents, which Mr. Meldrum, among others, has appealed to to account for the formation of cyclonic storms, is, taken by itself, inadequate; since any circular movements generated, in the manner supposed, by opposite currents, cannot receive from them a greater velocity than the mean velocity of the generating currents; and the theory leaves unexplained the spiral indraught of the air, which both Mr. Meldrum's charts of cyclones in the South Indian Ocean, and those which I myself, the late Mr. Willson, and Mr. Eliot, have prepared of storms in the Bay of Bengal, show to be an invariable as it is probably an essential feature of all such storms.[1]

[1] Mr. Piddington is usually regarded as an upholder of the hypothesis of the truly circular or tangential movement of the winds in cyclones, and not without reason; since, although he admitted, as a possibility, an occasional spiral indraught, he regarded this as non-essential, and equally admitted that the winds may occasionally blow outwards from the tangential direction. In most of his charts he does not give all the observed wind directions, but in that accompanying his first memoir, on the storm of June 3–5, 1839, he has done so. If any one will refer to this chart, and, leaving out of consideration Mr. Piddington's hypothetical circles, will draw for himself the most probable course of the currents in accordance with the charted wind arrows, he will soon convince himself that this course is sharply spiral, and also that Mr. Piddington, probably influenced by the erroneous hypothesis of circular rotation, has misapprehended the several positions of the storm-centre, and has assigned to the storm a course quite at variance with its real course, and equally so with that of any storm since observed in the same sea. The case is an interesting one, because Prof. Dove, misled by Mr. Piddington's error, has made this storm the basis of an erroneous explanation of the origin of the storm in his well-known work on "The Law of Storms," which has been translated by Gen. Sabine. Of course, in pointing out an error, I would in no way seek to disparage the admirable and laborious work of Mr. Piddington, whose great merits I most willingly recognise.

The storms generated in the Bay of Bengal afford unusual facilities for studying the genesis of cyclones. We have observatories round three sides of the bay, and the sea is, at all times of the year, traversed in all directions by numerous steamers and sailing vessels, which have furnished abundant logs. Did parallel currents play any important part in the production of the vortices, they could not possibly escape our notice. But we find that the antecedent conditions of a cyclone are light, variable winds and calms, with a nearly uniform barometric pressure all round the coasts; and only to the south, in the neighbourhood of the equator, is there any considerable movement of the air, viz., from the west. Under these circumstances, the pressure falls over some part of the bay; most frequently in the middle, and especially to the west of the Andamans. This region of falling pressure is characterised by torrential rains, with, at first, but little wind; but after a day or two (sometimes several days) of this weather, a cyclonic circulation is set up, with a marked indraught in the neighbourhood of the cyclone cradle, and thus the storm is generated.

Having regard to these facts of observation, it appears to me that it is in the condensation of the heavy rain (constantly noted as "torrential" in ships' logs) over the cyclone cradle, that we have the real source of the energy of the incipient storm. The hypothesis of parallel currents fails to provide this energy; for it is obvious that the deviation of the winds under the influence of the earth's rotation can furnish no energy, and can produce only a moderate barometric depression, the amount of which depends on the velocity of the original winds, and can be calculated by Ferrel's law. When this is reached, the system of pressures and wind-movements will be in equilibrium. If (and this I am not prepared to deny) a cyclone is sometimes generated between parallel currents, it must be that the energy of the storm is supplied from some other source, and what this is, is, I think, clearly indicated by the case of the Bay of Bengal storms.

It was first noticed by Mr. Eliot as a general fact, that, during the formation of a cyclone in the Bay of Bengal, little or no rain falls on the coasts; while, as already remarked, it is exceedingly heavy over the place of the storm's origin. The vapour generated over the bay, which, under other circumstances would be carried away by the winds and condensed over the land, is then condensed over the bay itself. The quantity of latent heat thus set free is enormous; and as Reye has shown, is ample for the production of the most violent cyclone. It would be erroneous to say that the air is thereby warmed and expanded, because, of course, the very fact of its vapour being condensed proves that it must be cooling; but Welsh's and Glaisher's balloon observations show that in a cloud-laden atmosphere, the vertical decrement of temperature is slow, as compared with that in a clear atmosphere; and the same fact is further illustrated by the temperature of hill-stations in the wetter parts of the Himalaya as compared with that of the plains at their foot. At Darjiling, for instance, the temperature from June to August (the season of greatest cloudiness and heaviest rainfall) is only 17° or 18° below that of Goalpara. In February and March (the driest months) it is between 23° and 24°. The explanation of these facts is afforded by the different rates of cooling experienced by saturated and unsaturated air, respectively, in an ascending mass of air which is expanding under a constantly diminishing pressure. Saturated, *i.e.*, cloud-laden and rain-condensing air at 80° cools only 20° by the work done during its ascent from the plane of 30 inches pressure to that of 20 inches pressure, say through 10,000 feet; whereas unsaturated air cools about 54° in the same ascent, the exact amount varying slightly according to the quantity of vapour it contains. The latent heat set free in the condensation of cloud and rain is then entirely used up in the work of expanding the cloud-laden air under a constantly diminishing pressure, and economises more than half (indeed, in the case adduced, nearly two-thirds) of the sensible heat which furnishes the energy to unsaturated air. Hence, an ascensional current, however small, once set in action in a nearly saturated atmosphere, such as exists over the Bay of Bengal during the formation of a cyclone, carries warm air to a greater height than in the clearer and drier atmosphere around the coasts, relatively raising the mean temperature of the former air-column, and of course reducing its weight. This differential effect goes on increasing, and the ascending current becomes more rapid, until the indraught below attains the conditions of a cyclonic storm.

Now, in the case of parallel currents, there must be between them a region of calm; and, if this is over a sea of high temperature, it is conceivable that, as in the Bay of Bengal, local condensation may proceed for a sufficient time unchecked to lead up to the formation of a cyclone; but, in that case, the cyclone will be generated, not immediately, as supposed by Mr. Barham, by the energy of the pre-existing winds, but by their affording conditions in which another and far more potent source of energy comes into play. Dinard, France, July 10

The Tasimeter and Magnetisation

After perusing an account, in a recent number of the *Scientific American*, of Edison's Tasimeter, it occurred to one of us to apply it to detect, and, if possible, to measure the elongation and shortening, which, as discovered by Joule, are produced in a bar of iron by magnetisation and demagnetisation. Accordingly to test whether the effect could be observed in this way, a rough specimen of the instrument was constructed, and with it some preliminary experiments made, an account of which may interest the readers of Nature. A small cylinder, about half a centimetre in length and diameter, of the carbon used for Bunsen's cells, rested with its ends which were slightly rounded, in contact with two brass plates, one of which was fixed to a rigid upright attached to one end of the base of the instrument, while the other, resting with one end on the base, formed a spring, which in its normal position just touched the end of the carbon. A coil containing four layers of insulated wire, six turns to the layer, was wound round a tube ten centimetres long and eight millimetres in diameter, and fixed with its axis in line with that of the carbon cylinder. A piece of iron wire was then placed in the axis of the tube with one end resting against the spring, and the other in contact with the end of a screw working in a nut fixed to a rigid upright at the end of the base remote from the carbon. By means of this screw the pressure of the iron bar on the spring, and consequently of the spring on the carbon, could be varied at pleasure.

A terminal of copper wire, was attached to each of the brass plates bearing on the carbon, and joined up so that the carbon, plates, and terminals formed one of the resistances of a Wheatstone's bridge, in connection with which a battery of one Daniell's cell and a very delicate Thomson's reflecting galvanometer were used. When the iron wire forming the core of the electro-magnet had been so adjusted that there was only a very slight pressure on the carbon, the resistances of the bridge were arranged to make the deflection of the galvanometer produced by the current from the battery nearly zero. The galvanometer and battery keys were then put down and the current allowed to flow through the bridge during the remainder of the experiment. The electro-magnet was then excited by the current from three of Thomson's Tray Daniells. This produced a deflection of the image on the galvanometer scale of about fifty divisions in the direction indicating a diminution of the carbon resistance, which must have been caused by change of contact produced by increased pressure on the spring. The length of the iron core of the electro-magnet had therefore been increased by magnetisation. When the magnetising force was removed the image immediately returned to its former position. As a verification that the diminution of resistance indicated by the bridge arrangement was caused by elongation of the iron core, the adjusting screw was turned forward through a very small distance, when the deflection was found to be in the same direction as before. When the screw was brought back the image on the scale returned towards its zero. Experiments with various strengths of current gave perfectly accordant results.

We hope by replacing the comparatively rough adjusting screw by a micrometer screw to be able to make some measurements of the exact amounts of elongation or shortening produced in a piece of soft iron or steel by given changes of magnetic intensity. It may be remarked that this method of measurement could be advantageously applied in cases where the amount of change of dimensions to be discovered or measured is very small, but the force which it could be arranged to produce abundant.

Thomas Gray

Physical Science for Artists

The curious phenomenon described by Prof. Brücke and Mr. Norman Lockyer, under the name of "les rayons de crépuscule," though rare and uncommon in the island of Ceylon, is

well-known to the natives under the title "Buddha's rays." It has also, I believe, been noticed in Cashmere. The phenomenon, which is very striking indeed under favourable conditions, is confined to the mountain region in the central parts of the above-named island, and is never, as far as I am aware, seen in the low country. It was therefore with considerable interest that I learnt that it is well known to the French, and had been seen by Mr. Lockyer at sea. In May, 1876, in a paper on "Remarkable Atmospheric Phenomena in Ceylon," read before the Physical Society and published in the *Proceedings*, I offered an explanation of this phenomenon, in accordance with the conditions under which it appeared. As this explanation is very brief, may I ask your permission to reproduce it *verbatim?*

"Not unfrequently in the mountain districts broad beams apparently of bluish light may be seen extending from the zenith downwards, converging and narrowing as they approach the horizon. This ray-like appearance is very similar to that seen before sunrise; only the point from which the rays proceed is *opposite* the sun: the rays themselves are very broad and blue in colour; and the spaces between them have the ordinary illumination of the rest of the sky. If we suppose in this instance that the lower strata of air are colder than the upper (a condition of the atmosphere which not unfrequently occurs in a tropical mountain district like that of Ceylon, where large currents of heated air sweeping up a valley cross another valley nearly at right angles and at a considerable elevation above it), the refraction spoken of in the case of Adam's Peak will be downwards instead of upwards. If, too, the observer be *below*, the veil of darkness will appear to him like a very elongated triangle, apex downwards, or broad ray, through which the blue sky beyond may be seen free from the palish illumination of the atmosphere, whilst on either side the ordinary illuminated sky will be seen. If now we suppose several isolated masses of cloud to partially obscure the sun, as was the case when I witnessed the phenomenon, we may have several corresponding inverted veils of darkness, like blue rays in the sky, all apparently converging towards the same point below the horizon. This apparent convergence of the beams is merely an effect of distance, as in the case of parallel rays of light from the rising or setting sun, the blue rays being practically parallel bands in the atmosphere devoid of illumination. It will be evident that conical-shaped clouds are not necessary to produce this effect. Isolated clouds of any massive form would be sufficient to throw the bands of shadow through the illuminated atmosphere, and refraction and perspective would do the rest. The above phenomenon is called by the Singhalese 'Buddha's rays;' and though, according to Sir Emerson Tennent, it is very varied in character and appears in different parts of the sky, yet I have only seen it when the sun was low at evening and when the rays converged to a point, apparently directly opposite the sun; and I do not think it possible for the phenomenon to be seen in any other position."

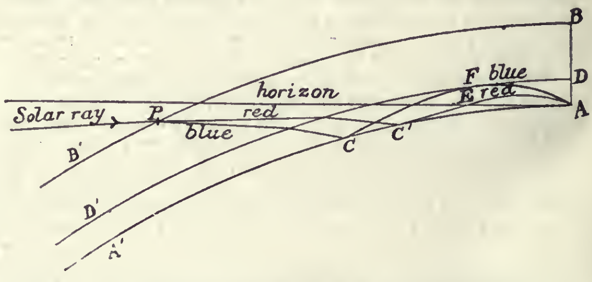
It will be seen that I thought it necessary to suppose a peculiar state of the atmosphere, in order that the shadows themselves might be sharply refracted downwards; indeed, I think, if the phenomenon can be produced under ordinary conditions, it would be much less rare in the island than it is. It may be mentioned that the sharpness and definition of the rays was most decided—far more so than the sunbeams and shadows are at sunrise or sunset—and that the position from which I observed the phenomenon was a ridge 4,500 feet high, overlooking a deep valley lying north and south, into which another valley running east and west opened at a high elevation, so that the warm air coming up the latter from the country below would overlie the cooler air of the first valley. I am not certain whether mountains a few miles to the west had any part in the production of the phenomenon, but the sun was certainly setting behind dense but isolated masses of cloud. With the above exception, it appears that my explanation is identical with that of Mr. Norman Lockyer and Prof. Brücke.

The reference in the above quotation to Adam's Peak is to the shadow which this isolated and cone-shaped mountain throws up into the sky at sunrise. The summit of this peak is 7,200 feet high, and overlooks the low country for fifty miles or more to the west. The shadow thrown by it at the moment of sunrise appears to lie horizontally over the land and sea for a distance of seventy or eighty miles. As the sun rises, the shadow rises and takes the form of a gigantic pyramid rising in the air and approaching the mountain, until at last it appears to fall over on the summit. The explanation which I offered of this was in principle identical with that of the mirage, the rays grazing the summit and sides of the mountain being refracted upwards, and thus leaving a portion of the atmosphere, similar in shape to the upper part of the Peak, unilluminated. This refraction is extremely likely to occur, as the difference in temperature between the air in the low country and on the top of the Peak is at least from 30° to 50° F. during the night and morning. The sudden vanishing of the shadow is, no doubt, due to the rays reaching the critical angle when the sun has risen to a certain height, and total internal reflection ceasing to take place. It may be mentioned that in both cases the shadows appear to be blue, but this, I imagine, is only the effect of contrast. This theory will, I believe, also explain the phenomenon of the spectre of the Brocken, which appears, I understand, under similar but less pronounced conditions.

The above appear to be very good instances of the illumination which the particles of air are capable of receiving, for it is evident that neither phenomenon would be visible if the atmosphere were perfectly pure.

Another phenomenon I shall be glad to refer to, as bearing on the subject of a perfectly clear sky at sunset. During the dry season on the West Coast of Ceylon, when the air is so free from moisture that even in houses close by the sea-shore the backs of books and sheets of paper curl up as if they had been placed before a fire, I have noticed, in looking westward over the sea immediately after sunset, that the sky has presented the appearance of an almost perfect spectrum extending from the horizon upwards for a very considerable distance towards the zenith (as far as I remember to within 20° of the zenith), a fiery red being lowest, succeeded by orange, yellow, green, and blue. With the exception of the red the colours were of the most transparent character possible; such as it seemed to me at the time it would be quite impossible to reproduce except with the prism or or diffraction lines.

The explanation which I would offer of this seems to bea directly on the question of the colour of the sky, and as it has not



I believe, been suggested, I shall be glad if you will allow it to appear. It may, however, be an old explanation, but I am not aware that it is. When a ray of sunlight passes obliquely through a thick plate of glass the issuing ray is found to have been dispersed during its passage, although on account of the overlapping of the spectra produced by the pencil it appears to the eye as white light, one edge where there is no overlapping being slightly red, and the other slightly blue. Now the atmosphere of the earth is such a parallel plate as this, and the solar rays falling on it very obliquely are dispersed into their component colours, the air being the dispersive medium. These colours cannot be observed (1) unless the obliquity is very great, for the colours overlap and white light is the result; (2) unless there is very little moisture in the air to absorb the more delicate colours and so prevent the dispersion effect being distinguished. In the case I refer to both these conditions were present in a remarkable degree. A reference to the figure will show at once the explanation offered for the spectral appearance of the sky. Let A A′ be the surface of the earth, B B′ the upper limit of the atmosphere, D D′ the upper limit of the more refracting layers of the atmosphere, A the point of observation, A X the horizon.

A solar ray striking the atmosphere at P will be refracted and dispersed, the blue ray striking the earth at C, and the red at C′. When these rays reach the surface of a sea that is nearly calm they will be reflected in various directions according to the angle at which they strike the wave-surfaces. Some will be reflected nearly vertically and will be lost in the clear sky, others will be reflected less vertically and will be subjected to the refracting influence of the lower strata of the air, the blue being refracted most and the red least. Thus the figure C F A may

represent the blue ray that suffers most refraction of all the blue rays, and C E A the red ray which suffers most refraction of all the red rays.

It thus appears that of blue and red rays reflected from the sea at the same angle, the former may reach the eye of the observer and the latter not, because, though the refraction is sufficient for the blue it is not so for the red ray, and it will be lost in the upper air. Consequently the blue rays will appear highest, and the red lowest, the other colours occupying intermediate positions according to their refrangibility. It is evident that any of these rays may be reflected too vertically from the sea, and so not be refracted to the earth again, but a considerable proportion will be thus refracted, and as has been said, more vertically inclined rays of the blue than of any other colour.

When we consider the effect of rays falling to the left of C, the phenomenon becomes more complicated. The same refraction, dispersion, and reflection take place, bnt the rays after reflection will mostly fall short of A, and strike the sea at various angles, producing a great variety of colour. It is not necessary for the effect that both the blue and the red from the same pencil of light should proceed to A, althongh this is shown for the sake of simplicity in the figure. It is sufficient if we know that blue rays, on account of their greater refrangibility, must of necessity be the highest, and the red, on account of their least refrangibility, the lowest.

If the above suggestion as to the dispersive power of the atmosphere be admitted, it is probable that the question of the colour and scintillation of stars will be directly affected by it.

Little Bromley, Manningtree, July 12 R. ABBAY

Zoological Geography—Didus and Didunculus

MR. SEARLES V. WOOD will, I trust, pardon me if I again take exception to the terms in which (*suprà*, p. 301) he still writes of *Didus* and *Didunculus*. These two birds do not belong to the same gronp of *Columbæ*. The fact that certain anthors may have included them under the designation of "ground-doves" is no proof whatever of their relationship, any more than it is of the relationship of either to any other birds so called—for instance those of the Neotropical genus *Chamæpelia*. I have studied pretty carefully the osteology of many forms of *Columbæ* with especial reference to their affinities. *Pezophaps* and *Didus* are of course nearly allied, though even these are not congeners. *Didunculus* is at least as distinct from them as from all other *Columbæ* with the possible exception of *Otidiphaps*, which last I have not had an opportunity of examining. Furthermore, I may remark that if Mr. Wood will but look at what has been published of the habits of *Didunculus* he will find that it is as much an arboreal as a terrestrial bird, so that the name of "ground-dove" is as unhappily applied to it as is that of *Didunculus* or its ridiculous translation, "Dodlet."

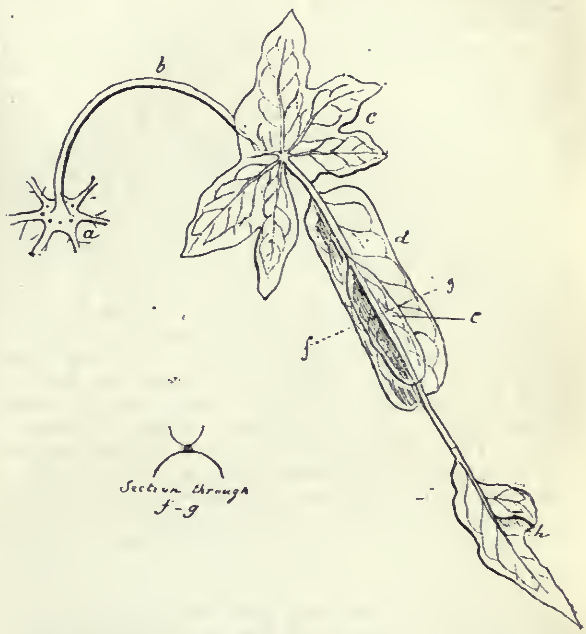
July 22 ALFRED NEWTON

Autophyllogeny

THE following case of *Autophyllogeny*, observed in a leaf of *Papaya vulgaris* (the well-known papaw-tree) appears to me of sufficient interest to be recorded in the columns of your highly interesting journal.

The letter *a* designates the central part of the primary leaf, corresponding to the apex of the petiole on the upper side of the blade. It shows some small warty protuberances, and from amidst them rises a new petiole (*b*), about six centimetres long and one and a half millimetre thick. This new petiole bears an accessory leaf of somewhat pentagonal outline (*c*), slightly crumpled and partially concave towards the upper side (the one directed downwards in the figure), as if there had been some tendency of forming a leaf pitcher. A little onwards two boat-shaped appendices are observed (*d* and *e*), the midrib or petiole forming their keel. They are real leaf pitchers, though of a rather uncommon form. The small lateral diagram represents the shape of the transversal section through *f* and *g*. The two leaves are opposed to each other by their upper sides, which are of a dark green colour; the concave parts are their under sides, as is proved by their pale green colour, which is generally the case in the leaves of the papaw-tree. The end of the petiole bears a pointed leaf (*h*), slightly contracted, and with a pitcher-like contortion on one side. The figure is about three-fourths natural size.

The case belongs to those mentioned by Masters ("Vegetable Teratology," 355, 445) under the heads of Pleiophylly and Enation from foliar organs. His explanation is certainly correct, as there cannot be any doubt that the accessory petiole *b*, but for its development in another plane, is a true homologon of the ribs of the primary leaf, and the minute warts round its base may be regarded as small or checked beginnings in this same direction.



The described anomaly does not appear to be rare [in *Papaya vulgaris*. I have observed several less-developed instances; the specimen here described was given to me by one of our students, Señor Ramon Documet. A. ERNST

Microscopy—The Immersion Paraboloid

As I am responsible for exhibiting at the Conversazione of the Royal Society, May 1, the immersion paraboloid as being "designed by Dr. Edmunds," I should wish it to be known that, since that date, my attention has been directed to evidence establishing Mr. Wenham's priority to the invention.

Before exhibiting the paraboloid at the Royal Society, I had Dr. Edmunds' assurance that he felt justified in requesting me to describe it as designed by himself. JOHN MAYALL, Jun.

224, Regent Street, London, July 16

THE GENESIS OF LIMBS[1]

III.

I HAVE found much resemblance between the skeleton of the ventral and the dorsal fins in *Notidanus*, in *Chiloscyllium*, and in *Raia*; also between the anal and ventral fins in *Notidanus*. The ventral fins of elasmobranchs generally are so different from their pectoral fins, and so much more like the azygos fins than the pectorals are, that they serve well to bridge over the differences between the orders of fins. At the same time the value of the link is enhanced by the fact that in the very peculiar genera *Callorhynchus* and *Chimæra* the ventrals resemble the pectorals in a very remarkable and exceptional manner. But perhaps the most instructive ventral fin is that of *Polyodon*, the skeleton of which consists simply of a double series of simple parallel rays without any attachment to a pelvic cartilage which is altogether absent.

These conditions, then, appear to obliterate the distinctions which are at first apparent between the skeletons

[1] Continued from p. 311.

of the azygos and paired fins themselves. It remains to speak of the supporting structures of the paired fins, the pelvic cartilages or bones, and the shoulder-girdle. At first it appears that a formidable objection against the similar nature of the paired and azygos fins may be drawn from the existence in the former of these supporting structures (which serve in the pectoral region to fix the pectoral fins to the axial skeleton), while no such connection ordinarily exists with regard to the azygos fins.

We have seen, however, that in *Pristis* and *Pristiophorus* the dorsal fin becomes directly continuous with the axial skeleton by a mass of cartilage large enough to warrant comparison with the shoulder-girdle itself, while it is more or less firmly united with the axial skeleton in *Rhyncobates*, *Squatina*, *Acanthias*, *Spinax*, *Chimæra*, and *Callorhynchus*. It must be admitted, however, that the attachments of the dorsal fin to the axial skeleton is horizontal, direct, and continuous, while the structure supporting the pectoral fin (the shoulder-girdle) extends vertically, is arched in shape, and only abuts at one end against the axial skeleton, while ventrally it joins its fellow of the opposite side. These characters seem at first to tell against the similarity of nature of the dorsal and pectoral fins. But three things should be borne in mind—(1) the pectoral fin-support could not continuously adhere to the axial skeleton antero-posteriorily without impeding the lateral flexure of the body in swimming; (2) the pectoral fins join the body at too low a level for their support to extend in horizontally to the skeletal axis; (3) and did it so extend inwards in a straight line, even obliquely, it would intrude upon the visceral cavity. For these reasons the pectoral (and ventral fins also) must (if they are to rest on a solid support to facilitate their flapping motion) have a narrow connection with a sustaining structure, which structure must not be directly continuous, in a straight line, with the skeletal axis. Moreover, to obtain a firm basis, this limb-support, if it is attached obliquely upwards to the skeletal axis, must have some point to abut against ventrally also. Thus such support must assume the form of a limb-girdle.

I think, then, that there is sufficient evidence to warrant a belief that the skeletal structures of the paired fins of fishes (and therefore the limbs of higher vertebrates also) are the result of the centripetal growth and coalescence of a primitively distinct, parallel series of cartilaginous rays, developed in a pair of lateral fins similar to those developed, and more or less coalescing and centripetally extending in the median fins above and below.

But what about the limb-girdles themselves? Mr. James K. Thacher,[1] of New Haven, Connecticut, has thrown out the suggestion that the pelvic bones and cartilages of fishes (and therefore limb-girdles generally) are also due to the further extension inwards of such centripetal growth. I regard this as a most happy suggestion, and adopt it myself. The mystery of the limb-girdles is thus satisfactorily explicable; they are neither modified branchial arches, extra-branchials, nor ribs, but parts *sui generis*, due to the ingrowth of originally superficial structures—exoskeletal hardenings which have grown inwards and become endoskeletal.

It remains to consider the question of the development of the original digit-bearing limbs, *cheiropterygium*, from the primitive fin, or *archipterygium*.

Gegenbaur at first regarded the elasmobranch fin as derived from a limb formed like that of *Lepidosiren*, but he subsequently adopted that of *Ceratodus* as the archipterygium, in which view Huxley coincides. The former naturalist, however, considers the shark's fin and the cheiropterygium as formed by the all-but complete abortion of the rays on one side of the ceratodus limb-axis, with the simultaneous shortening and thickening of that axis into a metapterygium, while the rays of the other side of the axis coalesce to form the meso and propterygium. The latter anatomist (Huxley), on the contrary, regards the ceratodus-limb axis as forming by its progressive shortening (or drawing-in) the mesopterygium of the shark's pectoral, and the limb-axis of the cheiropterygium, the latter being perfected by the atrophy of the proximal lateral rays and the hypertrophy of the distal ones, the distal end of the axis becoming the middle digit of the hand. Of these two views the latter seems to me much to be preferred, but it demands the unity of the *centrale* carpal ossicle, which now seems most probably to have been primitively double, as it is so not only in *cryptobranchus*, but also in both limbs of three species of Siberian Urodeles.[1]

I believe, however, that the limb of *Ceratodus* is far from showing us a primitive form, but is, on the contrary, a very special and peculiar structure, which is carried to a still more abnormal development in *Lepidosiren*. This view seems warranted by the theory of evolution, according to which air-breathing vertebrates must have been amongst later developments, and therefore have post-dated creatures with limbs more or less like those of Elasmobranchs and Teleosteans. The secondary

FIG. 17.—Pectoral fin of Acanthias (from Gegenbaur). *p*, propterygium; *ms*, mesopterygium; *mt*, metapterygium. The line drawn through *mt* indicates the fundamental line of the archipterygium or Ceratodus limb-axis.

fringing rays of the central limb axis of these Dipnoi may (as Peters pointed out as long ago as 1845) have arisen like the secondary fringing rays of the dorsal of the primary rays of the dorsal fin of *Polypterus*.

As to the formation of the cheiropterygium, I think that there are some reasons which favour the acceptance of the propterygium as the part in Elasmobranchs which has most relation to its primitive axis. Such are (1) the preaxial position, in the limb, of the line of the Propterygium—which is the line of support needed for the fore-limb of a quadruped which necessarily extends preaxiad, distally; (2) the apparently complete atrophy of the mesopterygium in *Chiloscyllium* and its partial atrophy in *Polypterus*, and other forms; (3) the large size of the propterygium in *Chimæra*, *Callorhynchus*, *Cestracion*, *Scyllium*, and *Pristiurus*.

On the whole, then, I feel much persuaded that vertebrate limbs have been formed as follows:—

1. Two continuous lateral longitudinal folds were developed, similar to dorsal and ventral median longitudinal folds.

[1] See *Trans.* Connecticut Academy, vol. i.i.

[1] See "Morphol. Jahrbuch" vol. ii. 3rd Heft, p. 421, Pl. 29.

2. Separate, narrow, solid supports, in longitudinal series, with their long axis at right angles with the long axis of the body, were developed in varying extent in all these four longitudinal folds.

3. The longitudinal folds become interrupted variously, the lateral folds so as to form two prominences on each side the primitive paired limbs.

4. Each anterior paired limb increased in size more rapidly than the posterior limb.

5. The bases of the cartilaginous supports coalesced as was needed according to the respective practical needs of the different separate portions of the longitudinal folds, *i.e.*, the respective needs of the several fins.

6. Occasionally the dorsal rays coalesced proximally and sought centripetally adhesion to the skeletal axis.

7. The rays of the hinder paired limbs did so more constantly, and ultimately prolonged themselves inwards by mediad growths from their coalesced base till the piscine pelvic structures arose.

8. The pectoral rays with increasing development also coalesced proximally, and thence prolonging themselves inwards to seek a *point d'appui*, shot dorsad and ventrad to obtain a firm support, and at the same time to avoid the visceral cavity; thus they came to abut dorsally against the axial skeleton and to meet ventrally together in the middle line below.

9. The lateral fins, as they were applied to support the body on the ground, became elongated, segmented, and narrowed.

10. The distal end of the incipient cheiropterygium either preserved and enlarged pre-existing cartilages or developed fresh ones to serve fresh needs, and so grew into the developed cheiropterygium.

11. The pelvic limb acquired a solid connection with the axial skeleton—a pelvic girdle—through its need of a *point d'appui* as a locomotive organ on land.

12. The pelvic limb became also elongated, and when its function was quite similar to that of the pectoral limb its structure also became quite similar. It became segmented in a way generally parallel with the segmentation of the pectoral limb, yet in part inflected inversely owing to its different mode of use.

Vertebrate limbs then are specialised differentiations of primitively continuous lateral folds, and might, for all we see, have been more numerous than two on each side, just as there are sometimes several successive dorsal fins which are all differentiations of a primitively continuous dorsal fold. The paired limbs and azygos fins may thus be all viewed as different species of one fundamental set of parts, *pterygia*, the sum total of which may be spoken of as the *sympterygium*. The paired fins of fishes are related to the limbs of higher vertebrates as structures which have diverged from their primitive condition to a less degree, not only because the piscine body is, as a whole, a more primitive structure, but also because their fins are still used for locomotion in that medium in which their primeval form—the continuous lateral fold—was first developed.

The amount of adaptive modification supposed will perhaps appear to some persons to be excessive. But I believe that the excessive plasticity of animal organisms is in general too little appreciated—a plasticity which results in, and is evidenced by, the many instances of homoplasy—the independent origin of similar structures. The existence of these adaptive modifications points to the existence of an intra-organic activity, the laws of which have yet to be investigated. The instances of serial and bilateral homology before cited from comparative anatomy, pathology, and teratology, also concur in pointing to an intra-organic activity, the laws of which are as yet unknown. The notion of an "internal force" is very repugnant to some of my contemporaries, but it is impossible to banish the idea of innate powers and tendencies, the existence of which is manifested in the inorganic world as well as in the organic world. We cannot conceive the universe as consisting of atoms acted on indeed by external forces, but having no internal power of response to such actions; and in "physiological units" and "gemmules" we have (as Mr. Lewes has remarked) "given as an explanation that very power which was pronounced mysterious in larger organisms."

Mr. Lankester[1] speaks of each animal function, even reproduction, as being "explained by its chemical and physical constitution," and of "the possibility of development" being "solely due to the physico-chemical constitution of protoplasm;" but he does not give the explanation, nor show how such constitution by itself gives developmental power. But even if he did the puzzle would but recur—By what process of the survival of the fittest did the inorganic substances obtain their various structures and innate powers?

To my mind the presence of a special internal force is made evident by the process of development; and I am disposed to concur with Milne-Edwards when he says: "Dans l'organisme tout semble calculé en vue d'un résultat determiné, et l'harmonie des parties ne résulte pas de l'influence qu'elles peuvent exercer les unes sur les autres, mais de leur co-ordination sous l'empire d'une puissance commune, d'un plan preconçu, d'une force préexistante."

Science, as I understand it, clearly points to the existence in each animal of something more than an amalgam of physical forces, to a force or principle which is *intra-organic*, as heat is in red-hot iron or light in the glowing photosphere of the sun—one with it as the impress on stamped wax is one with the material bearing such impress, though we can ideally distinguish the two. This power or force immanent in each living body, or rather which is the force of the body living (considered in an abstract way), is of course unimaginable by us, since we cannot by imagination transcend experience; nothing can be imagined by us which has not wholly or in its parts been the subject of our sensible experience, and we can have no sensible experience of this force, save as a living body acting.

It is on this account sometimes thought reasonable to deny its existence as a "figment of the intellect," forgetting the supremacy of the intellect over sense. Though no knowledge is possible to us except as following upon sensation, yet the ground of all developed knowledge is not sensational, but intellectual; it reposes ultimately not on "feelings," but on thoughts. Even in verification by sensation it is the *intellect* which doubts, criticises, and judges the action and suggestions of the senses and imagination. If then we have *rational* grounds for the acceptance of such a purely *intellectual* conception, the poverty of our powers of *imagination* should be no bar to its acceptance. We are continually employing conceptions of the kind—such, *e.g.*, as number, being, substance, causes, &c.,—conceptions perfectly intelligible, though transcending the powers of the imagination.

If, then, we should conclude that each living animal possesses a special and peculiar intraorganic force, and if such force be the imminent cause of nutritional balancings, and thereby of the facts of serial and bilateral symmetry, is it not reasonable to refer to that same cause directly adaptive modifications which, within limits, take place in response to the actions of the environment. The presence of such innate activity has been eloquently proclaimed by Hartman, though I would repudiate the contradictory term "unconscious intelligence," and would explain it in a way which differs widely indeed from his. But if such a power is the active agent in such organic adaptations, is it not reasonable to refer to it the special variations which result in the formation of new species? This is the very activity for the existence of which I have elsewhere contended,

[1] *Quarterly Journal of Micros. Science*, October, 1877, pp. 432, 433.

and to which I have applied the term "specific genesis," and it is this which I am more and more persuaded is the determining agent in, and therefore the one true cause of, the origin of species.

St. George Mivart

VARYING EXPERIENCES

I LOVE to repeat other people's experiments, and though not in the least doubting the accuracy of recorded observations in relation to bees, clover blossoms, and fertilisation, some years ago I covered patches with wire netting, to exclude the bees, for all, every flower I believe, perfected its seeds. I hope I have earned a reputation for accuracy in my statements of facts, and that it is not necessary for me to call witnesses. I will say here, however, that about that time I was visited by Dr. Sterry Hunt, ex-President of the American Association for the Advancement of Science, and together we uncovered one patch, and examined a few mature heads, with the result as above stated.

Recently I referred to Mr. Darwin's statement that one might as well sprinkle *Linum perenne* with so much inorganic dust as its own pollen, and stated that in my own garden a plant from the Rocky Mountains perfects seeds, and can only use its own pollen. An esteemed friend takes me to task[1] for this statement, remarking that I have overlooked that Mr. Darwin's facts are confirmed by Dr. Fritz Müller, in Brazil. This, in connection with remarks made on my clover experience, leads me to suppose that some believe I have offered the facts in opposition to those of Mr. Darwin. Nothing has been further from my thoughts. My point has been to show that plants or insects do not always behave in the same manner, on all occasions, and under all circumstances. I had an interesting illustration of this in March last. Having occasion to examine a large patch of chickweed (*Stellaria media*), I was surprised to find a number of honey-bees engaged in collecting pollen from them. For the past few years I have made a point of closely watching the behaviour of insects towards flowers, and I never saw honey-bees at work on chickweed before; I never heard of any one who has. I believe the chickweed has been given up to rigid self-fertilisation. Profusely among the chickweed grew *Draba verna*. The flowers of the two are about the same size, and both white, but the bees kept with strict exclusiveness to the chickweed. Yet I know that the Draba is not obnoxious to them, for in other years I have seen them at work on these flowers. Among them also were some *Capsella Bursa-pastoris* in bloom; but they also were passed by. I have never seen bees or any insects on the shepherd's purse, but from this chickweed experience it would not be safe to say none ever do visit them. The date of this visit of the bees was March 15, the thermometer 52°, spring scarcely begun, and only these three early plants in bloom.

I had a similar instance last autumn of the honey-bee's faith in the crust of bread theory rather than have no loaf at all. We had an open mild season, and towards Christmas, long after all other flowers were gone, the *Salvia splendens*, of which I employed a large number in the decoration of my grounds, was alone in flower. On warm days they were thronged with honey-bees, and I feel almost sure they had never visited my plants in other years when other flowers were to be had. The corolla tube is too long for the bees, so they had to bore the corolla from the outside. Boring from the outside is easy work for our large humble-bees. Almost all our flowers which offer the least obstruction to mouth entrance are robbed of their sweets in this manner. Even red clover is "tapped" by them in this way. But it was very hard work for the honey-bees, and I am sure that, only for the absence of other and easier worked flowers, I should not yet be able to say that I had seen the honey-bee bore from the outside of a flower, as the humble-bee generally does. There were white-flowered varieties of this species among the scarlet ones, but all were treated alike.

It seems to me that bees are not attracted to flowers by colour or fragrance merely, but that they are influenced by labour-saving ideas. A little experience teaches them how best to work in any species to advantage, and they will of course "make time" by keeping to this one till all are done. White varieties or scarlet varieties are all one to them, they can distinguish the species by other means than colour. And then they learn where to work to the best advantage, and only glean in poor fields after the richer harvest has been gathered. These considerations will naturally lead to different behaviour in different climates, and if I note these differences it is very far from my intention to offer them as contradicting the experiences of others; on the contrary, no one has a higher appreciation of their value.

Thomas Meehan

Germantown, U.S.

OUR ASTRONOMICAL COLUMN

Double Stars.—In Gilliss's catalogue of 290 double stars formed from observations made at Santiago, Chile, during the U.S. Astronomical Expedition in the years 1850-52, the conspicuous star α Eridani (*Achernar*), is reported to have been seen double, the companion being of the seventh magnitude, faint blue, and preceding, 3" south. We look in vain for mention of this companion-star in the observations of Herschel, Jacob, and Powell, and it is especially strange that it should not have been detected by the former during his sweeps with the 20-feet reflector at the Cape. The well-known binary p Eridani is less than 2° distant, consisting of two nearly equal components of between the sixth and seventh magnitude, and at first sight it might be inferred that by a typographical error the name of the star is wrongly given by Gilliss. His position, however, is that of α Eridani, and further we happen to possess measures of p Eridani by Jacob, at the precise epoch of the Santiago observation 1850·79, giving for the angle 268°·7, and distance 4"·32; the *comes* therefore could hardly be described as preceding, 3" south, but might rather be said to precede on the parallel. This would indicate that the star intended is really *Achernar*, and it must be left for further observation to decide upon the accuracy or otherwise of the statement made by Gilliss. If the companion exists it would be of interest to know its present position; the proper motion of the principal star is very insignificant, and marked difference from Gilliss's description would be suspicious as showing a binary character. Still it is to be observed that there are considerable discordances between the angles and distances of many of the stars in the Santiago catalogue and those in Herschel's Cape volume. The former are not the results of actual micrometrical measures. It is stated that the catalogue was formed by plotting, on a large scale, the differences of right ascension and declination of the components of the double-stars observed with the transit-circle ($4\frac{1}{2}$ inches aperture), and then measuring from the drawings the angles of position and distances. In most cases the right ascensions and declinations observed are given in the preceding catalogue of 1,963 stars, and the results of the graphical process can be verified by calculation. In looking through the list of double-stars the reader will note differences from Herschel's data, which are not always easily explained by possible motion, though, as some of the stars have not been properly measured since Herschel's epoch, there will remain a doubt as to the cause of these differences. As instances in point, we may mention the following numbers of the Cape cata-

logue:—3860, 3966, 4119, 4281, 4538, 4667, and 4770. Probably Mr. Ellery at Melbourne, or Mr. Todd at Adelaide—both of whom are understood to be partially occupied with measures of the southern double-stars—may eventually clear up the uncertainties which characterise the results published by Gilliss.

While referring to the catalogue of stars observed at Santiago, it may be remarked that the majority of the large proper motions shown by comparison with Lacaille are proved to arise from errors of observation on his part, when we examine the particular cases with the aid of the valuable volumes which Mr. Stone is so regularly issuing from the Royal Observatory, Cape of Good Hope. When the volumes containing the observations made in 1876 (N.P.D. 135°–145°) and in 1877 (N.P.D. 125°–135°) are published, Mr. Stone will have placed in the hands of astronomers the means of investigating the proper motions of a large number of southern stars, which can hardly fail to lead to conclusions of much interest and importance. We are not justified in supposing that in Groombridge 1830 we have the case of largest proper motion in the northern hemisphere, and as to the proper motions of southern stars our knowledge is yet but very limited, and very conspicuous instances of rapid translation may remain to be detected amongst the telescopic stars of the southern heavens.

THE NEW COMET.—The telegram notifying the discovery of a new comet, and forwarded by the Smithsonian Institution to M. Mouchez, Director of the Observatory at Paris, is in these terms:—"Discovery, by Lewis Swift, of Rochester, of a large and faint comet, July 7, 1878, at 2h., in 17h. 40m. right ascension and 18° north declination, with slow motion towards the southwest; neither tail nor nucleus, but a central condensation. Query, is it the Tempel comet?" In communicating this telegram to the Academy of Sciences, on July 15, it was stated that the sky had been overcast at Paris, and therefore no opportunity had been afforded for verifying the discovery, and further that, notwithstanding an immediate intimation was given to the principal European observatories on receipt of the telegram at Paris on July 9, M. Mouchez had not heard of any observation elsewhere.

In this country several practised observers have failed to detect the comet, though the skies have been at times very favourable. The query in the American telegram, referring to Tempel's comet, might suggest that the declination of the comet was *south*, but, upon submitting the point to calculation, it does not appear that this change will afford an explanation of the want of success. If Tempel's comet were in perihelion about noon on August 11, its right ascension, at the time of Mr. Lewis Swift's discovery, would have been as he estimated it, but the declination would not be more than 7½° south. A large, faint, diffused nebulosity, however, is easily overlooked—the best chance of detection, when the position is not precisely known, being probably afforded with the "comet-seeker," by which we mean such an instrument as is (or was formerly) constructed by Pistor and Martins, of Berlin. Mr. Lewis Swift was already the independent discoverer of a comet, and is not likely to have been mistaken or misled by any optical illusion on this occasion.

[Since the above was written we learn that Prof. Winnecke re-observed the periodical comet of Tempel at Strasburg on July 20, the position obtained that evening indicating that the perihelion passage will not take place until September 6, or between five and six days later than the date fixed by M. Schulhof's calculations, which is, perhaps, as close an agreement as was to be expected, since the observations in 1873 did not suffice for the very accurate determination of the mean diurnal motion. The comet was from 2′—3′ in diameter, with nuclear condensation. When the mean anomaly is so corrected that the observed and computed longitudes for July 20 are made to agree, the latitudes differ only one minute, proving that M. Schulhof's other elements are very near the true ones. The following places for midnight at Greenwich may facilitate observations:—

	Right Ascension.	North Polar Distance.	Log. Distance from Earth.	Sun.

The intensity of light does not sensibly vary during the above interval.]

METEOROLOGICAL NOTES

TO the meteorologist the recent discussions in Parliament and out of it regarding the salubriousness or insalubriousness of the climate of Cyprus have been, if not instructive, at least amusing, the amusement arising from the circumstance that positive information was not forthcoming in support of the strong statements made on both sides. Thanks, however, to the Scottish Meteorological Society, we have trustworthy information on the subject, that Society having established there one of its foreign climatological stations in 1866, where, for about four years, observations were made by Mr. J. B. Sandwith, H.M. Vice-Consul, and the results regularly published in the Society's *Journal*. Summarising these results, we learn that the annual rainfall is about 14 inches, nearly the whole of which falls from November to April, notably in November and December, that no rain falls in June, July, and August, and only trifling amounts, but occurring rarely, in May and September. There is thus practically five rainless months in the year in Cyprus, the rainless summers being a feature in its climate common, as we have recently had occasion to remark, to the climates of the Mediterranean regions south of latitude 43° (NATURE, vol. xviii. p. 287). Comparing it with the coasts of Syria opposite, its winters are milder and its summers cooler; and the decidedly insular character of its climate is further apparent from the fact that the coldest month is February, with a mean temperature of 52°·8, being about equal to that of London in the middle of May, and that the mean temperature of August is nearly as high as that of July, both being about 81°·0, which is approximately the summer temperature of Algiers, Alexandria, Athens, and Constantinople. During these four years the highest recorded temperature in the shade during any of the months was 96°·0, except June, 1869, when, from the 21st to the 25th, the mean temperature at Alethriko, 3½ miles inland from Larnaka, reached 95°·5, being about the average summer temperature of the Punjab, rising on the 24th to a maximum of 105°·0. On the same day the temperature rose to 100°·0 at Larnaka, and to 103°·5 at Jerusalem, 2,500 feet above the sea, the period being characterised as one of unprecedented heat and drought over the whole of the regions bordering the Levant. It is obvious to remark that much may be done in mitigation of the effects of the summer heat, just as has been done in countries similarly circumstanced, by the establishment of sanataria among the mountains, and by carrying through agricultural improvements and engineering works, which would at the same time contribute to the material prosperity of the island.

PROF. LOOMIS, in a ninth Contribution to Meteorology, handles admirably a question of first importance in

the practical bearings of the science, viz., the relations of the barometric depressions and storms of the Pacific States to the storms east of the Rocky Mountains. As regards the twenty-seven storms whose courses he has traced, it is probable that the great majority, if not the whole of them, were first formed over the Pacific Ocean. In each of the twenty-seven cases (with perhaps one single exception) the storm crossed the Rocky Mountains, and was thence tracked across the United States to the shores of the Atlantic, subject, however, in some cases to modification in its progress. It is scarcely possible to overrate the importance of these results in the practice of weather telegraphy and on questions affecting the general movements of the atmosphere. For we see here that an unbroken mountain-range of at least 6,000 feet in height does not stop the eastward progress of these barometric depressions and storms; neither do mountain-ranges of more than 10,000 feet in height, broken as in North America, present an insuperable obstacle to the onward course of these phenomena. The mountain-ranges between the Pacific and the Mississippi present obstructions to the formation of a system of winds of any great geographical extent; and hence, probably, barometric depressions are not so great over this uneven and broken region as over the vast plains of the Mississippi and eastern States, where there are no mountain barriers to interfere with the formation of a system of circulatory winds over areas 2,000 miles in diameter.

CHEMICAL NOTES

Influence of Temperature on the Rotatory Power of Quartz.—Following up the researches of Lang and Fizeau, Sohncké has found (*Ann. d. Phys. Chem.*, N.S. III. p. 516) that the increase in rotary power in quartz, with increase of temperature, is not directly proportional to the temperature, but is less at lower than at higher temperatures. For the crystal he experimented on he determined the following formula:—

$$\phi = \phi^{\circ} (1 + 0{\cdot}0000999\, t + 0{\cdot}000000318\, t^2),$$

where ϕ° = the rotatory power of the same crystal at 0°; and he further found that the relative increase of power in the plane of polarisation was the same for all colours up to 170°. To see whether the octahedral system presented the same phenomena he also examined common salt, and obtained similar but more strongly-marked results.

Change of Indices of Refraction in Mixtures of Isomorphous Salts.—M. Dufet, in the *Comptes Rendus*, lxxxvi. 881, gives a most interesting account of some experiments he has carried out on the above subject, partly in continuation of such work as that of Senarmont, Topsoë, and Christiansen (*Ann. Chem. Pharm.*, 1874). Instead of examining simple isomorphous salts the author has taken mixtures containing varying quantities of magnesium and nickel sulphates, but of known composition. Working with such bodies he has determined that "the differences between the indices of a mixture of two isomorphous salts and those of the component salts are inversely proportional to the number of equivalents of the two salts entering into the mixture." In his calculation, M. Dufet has taken as an equivalent the number 111 or one equivalent of $SO_4.7HO$. He considers the law of variation of the index as a consequence of Gladstone's law: the refractive energy $\frac{n-1}{D}$ of a mixture of two bodies with no chemical action on one another, being the sum of the refractive energy of the component substances. According to M. Dufet, isomorphous salts crystallising together, form mixtures presenting analogies to a certain extent comparable with liquid mixtures, where the physical properties are the mean of those of the components; this, however, is only true up to a certain point.

Allotropic Modification of Copper.—By the electrolysis of a solution of about 10 per cent. of copper acetate Schützenberger has obtained an allotropic variety of copper somewhat remarkable in its physical and chemical properties. During the electrolysis the surface of the negative platinum electrode which faces the positive copper electrode becomes covered with a layer of the allotropic modification of the metal, whilst the other side of the electrode is covered with a deposit of ordinary copper. The allotropic modification forms metallic glittering scales with roughened surfaces on the side next the solution; should the electrolysis be carried on long enough, beautiful tree-like forms are deposited on the edge of the negative electrode, which gradually ramify over to the positive electrode. The allotropic copper is less red than the ordinary variety, possesses surfaces without malleability, and can be reduced to an extremely fine powder. Its density, 8 to 8·2, is higher than that of the ordinary variety, which is about 6·9. It oxidises rapidly in the air, becoming at once iridescent, and finally of an indigo blue colour; when exposed to the air as a powder it becomes black, changing finally into the oxide. According to the author it becomes reconverted into the ordinary form of copper by heat, or exposure to certain chemical agents.

Saccharose.—M. J. Motten has recently brought forward a paper, entitled a "Contribution to the History of Sugar (Saccharose)," in which the author discusses the action of light and of a temperature of 100° Cels. on solid and dissolved sugar, proving that the light alone does not invert dissolved sugar, and also that a temperature of 100° does not alter dry sugar. On the other hand solid sugar imperfectly dried, and dissolved sugar are altered under the influence of that temperature; oxygen is then absorbed, and carbonic acid evolved, but more slowly than it was often supposed.

Heat Evolved in the Formation of Isomeric Bodies.—M. Berthelot has given several communications to the Chemical Society of Paris, relating to the above subject. He finds that in general nitro compounds and isomeric nitric ethers appear to be formed with the disengagement of very unequal quantities of heat; the transformation of ethers into nitro compounds disengage approximately thirty heat units, at the same time undergoing increase of density and rise in the boiling point. In the case of metameric acids, as butyric, isobutyric, valerianic, &c., combining with the same base, his numbers show that the heat disengaged is precisely the same in the various cases which he describes. Approximately equal numbers are also obtained in the case of the chloro and bromo derivatives of these acids. There is very little difference also in the heat disengaged in the transformation of isomeric alcohols into isomeric aldehydes. The general results of his experiments, covering about thirty compounds, including alcohols, aldehydes, fatty acids, and their salts, chloro and bromo acids, &c., point to the conclusion that isomeric bodies having the same chemical function are formed with nearly identical disengagements of heat, their reciprocal metamorphosis disengaging very little heat. Finally, the same approximations exist in the formation of their isomeric derivatives.

Chemical Changes Taking Place during the Ripening of Grapes.—From experiments lately made on the transformations of the grape, and the exchanges between it and the surrounding atmosphere, MM. Saint Pierre and Magnien conclude that grapes at the time of their maturation liberate carbonic acid both in darkness and in light, the quantity produced being always superior to the quantity of oxygen consumed, if the experiment be long enough. This liberation occurs as well in an inert

gas as in air. Grapes are capable of absorbing or losing water when kept in a moist medium or in a dry medium. As maturation advances, the acids diminish and the sugar increases. The mechanism of maturation is stated to be this :—Acids and glucose are formed in the plant, and the sap conducts them to the grape ; the acids are consumed in it, while the sugar is concentrated. When the maturation is very advanced, the sugar is consumed in its turn.

RIPENING OF GRAPES AFTER REMOVAL FROM THE VINE.—In the *Gazetta chimica Italiana*, vii. 517, some experiments by M. Pollacci are described, in which he finds that the process of ripening continues for a certain time after the grape has been removed from the parent plant. The bunches of fruit removed were, as far as possible, equally divided, and the quantity of glucose and acid determined in the freshly-gathered grapes, as also in portions kept in the shade for some ten or twelve days. In all the portions which had been kept, the glucose had increased, whilst the amount of acid had diminished, showing that a certain amount of ripening action had taken place ; this action, however, ceases after a time, the ripening never attaining full maturity.

USE OF METHYL CHLORIDE FOR THE PRODUCTION OF LOW TEMPERATURES.—At a recent meeting of the French Physical Society, M. Vincent called attention to the use of chloride of methyl for production of low temperatures. It may be extracted in large quantities and cheaply from the products of beet-root molasses. It is normally gaseous, and liquefies under about four atmospheres pressure, when it may be conveniently carried about in iron or copper vessels, a store of cold at easy disposal. On opening a cock the liquid will flow out and give a bath at $-23°$, its boiling temperature under atmospheric pressure. If the vaporisation be intensified by a current of air, the temperature descends to about $-55°$. M. Vincent has arranged an apparatus for utilisation of such cold. He incloses two or three kilogrammes of liquid chloride of methyl in a double wall enveloping a bath of alcohol or chloride of calcium in solution, and protected exteriorly by an isolating layer of cork raspings. To obtain low temperatures, a cock is opened to allow communication of the double envelope (through a caoutchouc tube) with an air-pump.

FORMATION OF HYDROCARBONS BY THE ACTION OF WATER ON MANGANESE IRON ALLOYS CONTAINING CARBON.—Cloëz found that by acting on Spiegeleisen with dilute sulphuric acid bodies resembling the petroleum hydrocarbons were formed. On trying the action of pure water at 100° no results were obtained, while at 250° with super-heated steam, a certain action was perceived which increased with the temperature, being completed at a dark red. The hydrocarbons, however, were again decomposed. The same author has since tested a series of manganese alloys, and finds that the best results are obtained by means of one containing roughly Mn 85, Fe 6, C 3·5, Graphite 4, Si 1·1. Small portions of this, treated with boiling water, decomposed the latter with the evolution of hydrogen, oily drops being simultaneously formed, and the gas burning with a luminous flame showed the presence of hydrocarbons. Another alloy of nearly similar composition gave the following results: the flask contained slightly alkaline water with a mixture of iron and manganese oxides in suspension; the liquid hydrocarbons in the condenser were similar to those previously found, the gases also burning with luminous flames. He has thus shown that water alone at the proper temperature decomposes manganese iron alloys containing carbon.

ACTION OF BORON FLUORIDE ON CERTAIN CLASSES OF ORGANIC COMPOUNDS.—This body has been found by Fr. Landolph to combine in definite proportions, equivalent for equivalent, with certain classes of organic bodies such as aldehydes, acetones, and also with camphor. For his experiments the particular substances examined were ethylic, valeric, and benzylic aldehydes, ordinary acetone, euodic aldehyde (oil of rue), and ordinary camphor. In all these cases considerable disengagement of heat was manifested in the combinations of the several substances. By the action of the fluoride on acetone two products are obtained, the one boiling between 130°-140°, this being, according to the author, the most definite; another compound, however, exists which boils at a temperature of 160°-170°. The first is a fluid of a syrupy consistence and yellow-green colour ; it burns readily, giving a green flame, and is entirely decomposed by water. The compound, with ethylic aldehyde, ethylen fluoboride, $C_2H_3BFl_2$, undergoes decomposition when treated with water, into a body with a peculiar ethereal odour, the composition of which, the author thinks, may probably be C_2H_5Fl.

GEOGRAPHICAL NOTES

IN the just-published number of the Royal Geographical Society's *Proceedings* we find some useful remarks by Mr. F. Galton, on what has recently been done and what is further required for the advancement of geographical teaching. First and foremost, he says, is the publication of that excellent book by Prof. Huxley, "Physiography," which, starting from the simplest elements, led students steadily on to the higher conception of physical geography and the most recent discoveries in it. Next, Sir Walter Trevelyan, a former Secretary of the Society, had felt so much the necessity of a better form of text-book for geographical teaching that he had placed a handsome sum at the disposal of the Council to procure, if they were able to do so, the compilation of a really good county geography, to serve as an example for other similar works to be used in elementary schools. Turning to what is required in the future, Mr. Galton mentions that they have received a letter from a master of one of the great public schools, urging them to plan a system of diagrams explanatory of different physical features. His own opinion, Mr. Galton says, is that what is most urgently needed is some simple and well-methodised system of experiments, suited to illustrate lectures on the main features of physical geography. He has no doubt that an extension of the methods of illustrating the facts of physical geography—as used by Prof. Tyndall and Dr. Carpenter—on a small scale and on a lecture-room table, is perfectly feasible. Thus, as every thunder-shower shows in the streets the phenomena of erosion and deposition, he has no doubt that, on a lecture-table, with a can to supply water, and with a certain quantity of sand, gravel, and clay, all the main phenomena of river-action, such as the sifting of materials, the stratification of deposits, and the formation of deltas, might be successfully shown.

MEANS have recently been found, we learn from the *South Australian Register*, for still further increasing the usefulness of the Hon. (now Sir) T. Elder's camels on the far northern stations with which he is connected. The experiment of using them for draught purposes has been tried, and recently two teams of six camels drew loads of 5¼ tons each from Beltana to Port Augusta. The plan adopted is to yoke the animals together something after the manner in which bullocks are coupled, and one man only is required to manage each team. It has been found that the camels thrive well in the northern country ; the number originally imported several years ago was about 100, of which the greater part died, as the land, by its comparative richness, presented too great a contrast to their native soil ; there are now, however, about 400 of their descendants at Lake Hope, Umberatana, Beltana, and other stations in the far north, and the race seems to be thoroughly acclimatised. The camels have already been

found to be of great service in exploring expeditions, and they are still being used by parties engaged in opening up new pastoral country. Several of the animals have recently been lent to squatters for expeditions to the country on the Western Australian border, the MacDonnell ranges in Central Australia, and elsewhere.

FROM the new issue of Behm and Wagner's "Bevölkerung der Erde," we learn that the present population of the earth is estimated at 1,439 millions as compared with 1,424 millions given in the previous issue. This increase results mainly from the recent censuses which have been taken in several countries. This population is divided among the several continents as follows:—Europe, 312,398,480; Asia, 831,000,000; Africa, 205,219,500; Australia and Polynesia, 4,411,300; America, 86,116,000. This new issue contains the first map we have seen of New Zealand with the recent division into counties, in substitution for the old division into provinces. A census according to counties cannot, however, be taken till 1881. The North Island has thirty-three and the South Island thirty-one counties.

MR. STANFORD has issued a very useful shilling Treaty Map of South-Eastern Europe and Armenia, showing the boundaries of the New Bulgaria and Eastern Roumelia, the accessions to Austria, Russia, Montenegro, Servia, and Roumania, and all the other changes which have been made by the recent Congress. The new features are shown with unmistakable clearness. Mr. Stanford is also preparing a large scale map of Cyprus, showing not only the physical, but also the geological, agricultural, and other features of our latest acquisition.

AN expedition to the mouth of the Yenisei River left St. Petersburg last week. Principally at the instigation of a Moscow commercial firm eight steamers laden with corn, spirits, nitre, and other goods will soon start on the new sea-road to Siberia, their return cargoes consisting of wood and tea.

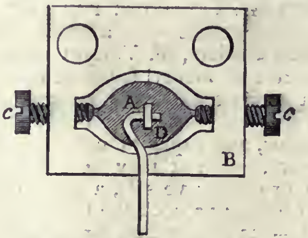
MR. GORDON BENNETT proposes to send the yacht *Dauntless* on a voyage of discovery to the Polar Seas, *viâ* Spitzbergen, in addition to the *Pandora*, which will attempt to reach the Pole by another route.

A METHOD OF RECORDING ARTICULATE VIBRATIONS BY MEANS OF PHOTOGRAPHY[1]

THE object of this paper is to describe a method of obtaining photographs of minute vibrations on a magnified scale.

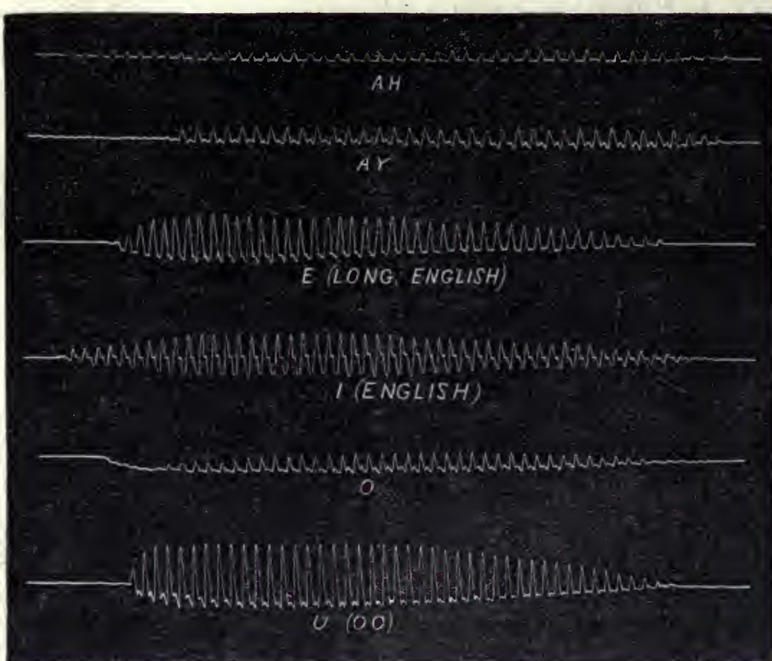
A plane mirror of steel, A, is supported by its axis in the metal frame B. The ends of the axis are conical, and carefully fitted into sockets in the ends of the screws C, C. On the back of the mirror is a slight projection, D, pierced by a small hole.

The vibrating disc, as hitherto employed, is a circular plate of ferrotype iron, 2¾ inches in diameter, screwed to the back of a telephone mouthpiece of the form invented by Prof. John Peirce, and now universally used. From the centre of the back of this disc a stiff steel wire projects, the end of which is bent at a right angle. This wire serves to connect the vibrating disc



Back view of mirror, actual size.

with the mirror by hooking into the hole in D, as represented in



the figure. The mirror frame and the vibrating disc are kept in a fixed relation to each other by a block of hard wood, to which both are firmly screwed. The mirror is set with its axis parallel, and its reflecting surface perpendicular, to the vibrating disc.

A heliostat sends a beam of sunlight horizontally through a small circular opening. This beam passes into a dark closet, and at a distance of several feet from the circular opening falls upon the mirror above described, placed with its axis inclined 45° to the horizon. The rays, reflected vertically downward, pass through a lens at whose focus they form an intensely luminous image of the circular opening.

[1] The text abridged for NATURE by Prof. E. W. Blake, of Brown University, from a paper in the *American Journal* for July. The illustrations (except mirror) from photos supplied by Prof. Blake.

HOW
DO
YOU
DO

A carriage moving smoothly on four wheels travels beneath the lens at such a distance that the sensitised plate laid upon it comes at the focus for actinic rays. A uniform velocity is given to the carriage by a string fastened to it and passing over a pulley. To this string a lead weight, just sufficient to balance friction, is permanently attached, while a supplemental weight acts at the beginning of motion and is removed just before the sensitised plate reaches the spot of light above described.

The velocity attained by the carriage is determined by placing a sheet of smoked glass upon it and letting it run under a tuning-fork (Ut. 3—512 v. s.) provided with a pointed wire. In every case more than 200 vibrations were counted and measured, and careful comparisons made between the earlier and later ones, so as to be certain of the uniformity of the motion.

From the description it will be evident that when the carriage alone is in motion a straight line will be photographed upon the plate. On speaking into the mouthpiece the disc is set in vibration, each movement causing change of angular position of the mirror, the reflected light moves through twice this angle, and the resulting photograph gives us the combination of its motion with that of the carriage. The carriage should run from *right* to *left*. The negative (examined from the *glass* side), and prints taken from it, then give the syllables in their proper order, and show movements of the disc from the speaker by lines going from the observer. The arrangement of my dark room compelled me to make my carriage move from *left* to *right;* hence, in the figures given, forward positions of the disc are represented by the lower portions of the curves.

The general character of the curves obtained is shown in the accompanying figures, which are the actual size of the originals, except that representing the vowel-sounds, which is about one-half (0·56).

The velocity of the carriage for the vowel-sounds was 21½, for *Brown University*, 40, and for *How do you do*, 14 inches per second.

In the mathematical discussion of these curves the abscissas are measured by the known velocity of the carriage, and serve to determine the *pitch*, the ordinates represent the amplitude of vibration of the centre of the disc, magnified 200 times in the photographs. The reduction of scale makes the magnifying in the woodcuts only 112 times.

The ordinates are not strictly straight lines, but parts of the vertex of a parabola, and closely approximate to circular arcs whose radius is the focal length of the lens employed. In the figures given, the centres of curvature of these arcs is at the right hand.

With an ordinary tone of voice an amplitude of nearly an inch is obtained, implying a movement of the centre of the disc of ·005 inches as determined by actual measurement.

By varying the accelerating weight and its fall, any manageable velocity may be given to the carriage. Each syllable requires for its articulation about one-fourth of a second, hence the plates must be quite long when the velocity is great. I employ plates two feet in length, and find that velocities from 16 to 40 inches per second give good results. The action of the light is, however, inversely as the velocity. To compensate for this, the size of the circular opening admitting the light may be increased. This, of course, causes an enlargement of the luminous image, and apparently involves an injurious widening of the line traced, but, as observed by Dr. Stein in his experiments, the effect of velocity is to narrow the line photographed, since the maximum exposure is in that diameter of the circular image which lies in the line of motion. This is a great advantage, since a variation of velocity in the vibration is marked by the widening of the line, often more clearly than by the form of the curve.

I have employed the ordinary photographic process, not attempting to obtain special sensitiveness. The brightest sunlight is required, a slight haziness interfering seriously with the result. My heliostat employs two reflectors of ordinary looking-glass, and the loss of light is considerable.

Are *all* the audible elements of speech traceable in these records? in other words, is the record complete? I am not prepared as yet to answer this question definitely, but the following experiment leads me to doubt whether an affirmative answer can be given, while at the same time it illustrates in a striking manner the sensitiveness of the ear. The mirror was attached to the disk of a *receiving* telephone and a photograph taken from it while the instrument was talking audibly. The resulting record was almost a smooth line, showing but very slight indications of movement of the mirror. It would therefore appear that there are distinctly audible elements, which are too minute to be recorded by this method. It is to be noted, however, that the width of the line traced where the vibrations are extremely small, is so great as to mask the curvature, so that the experiment just cited is not entirely fair.

The clearness and beauty of the curves obtained can hardly be appreciated without inspection of the originals. Their complexity and variety open a large field for investigation, and they seem to offer the means of analysis of articulate speech.

THE PHONOGRAPH AND VOWEL SOUNDS

I.—THE VOWEL SOUND Ō.

In a recent letter to NATURE we gave a short account of what we believed to be the existing theories of vowel-sounds. In the present paper we will state the chief results as to the vowel *ō* of our investigations made by means of the phonograph.

The experiments were made as follows:—The vowel under consideration was spoken or sung at a given pitch, determined by a piano, while the barrel of the phonograph was turned at a definite speed, regulated by means of a metronome. The indentations made in the tin-foil were then mechanically transcribed, so as to give curves representing a magnified section of the impressions. The curves were magnified by a system of compound levers, and recorded by an arrangement resembling that of Sir William Thomson's siphon-recorder. The details of the apparatus are described in a paper laid by us before the Royal Society of Edinburgh. The vertical ordinates of the curves drawn in ink, as shown below, are about 400 times larger than the corresponding indentations in the tin-foil, while the longitudinal ordinates are multiplied about seven times. The slowness of the motion by which the transcript was made enabled us to avoid all error due to inertia of the working parts, and the total absence of friction between the marking siphon and the paper allowed the transcript to be made without employing such a pressure on the tin-foil as would sensibly alter the indented curves. This fact was in each case tested by making the phonograph speak the vowel after it had been copied. All transcripts were rejected if the tin-foil did not continue to give the sound clearly after being used to produce these curves.

We employed various sizes of chamber and of mouth-piece, various thicknesses of tin-foil, and various discs as receivers. The curves now given as transcripts were found to be practically independent of variations in all these conditions. We are therefore of opinion that the curves do really represent the motion of an air-particle when the vowel is spoken, and that these curves may be regarded as sufficiently unaffected by any periods of vibration proper to the disc and springs employed, or to the air in the chamber of the mouth-piece, to constitute a true record of the essential parts of the vowel-sounds. This may be inferred from the remarkable constancy in the results obtained, with great variations in the conditions of the experiment, and from the fact that the indentations, after being copied, were in each instance able to give back the vowel-sound distinctly.

Fig. 1 gives a series of curves produced by a single baritone voice singing *ō* on a series of notes ranging from G to *f′*. This series has been selected because the voice was of good quality and considerable range.

After the curves were obtained they were subjected to harmonic analysis. One period was divided into twelve equal parts, and twelve ordinates were drawn and measured at right angles to a line joining two successive maximums or minimums. The numbers so determined enabled us to calculate the amplitudes of the first *six* partial tones.

Table I. gives these amplitudes for the above series of *ō*'s, obtained by analysing one period chosen out of the hundreds of similar periods which were given by each utterance. An examination of the curves and of the table will show that the change in character from note to note is fairly gradual and consistent throughout. The figures are arranged so as to show the absolute pitch of each of the six partial tones.

Voices of very different qualities were tested in the same way throughout the same range or such parts of that range as were within their compass.

Too much space would be taken up if we were to give here all the results obtained. It may be briefly said that the several voices agreed very fairly in respect of the partials composing the vowel at each pitch, that is to say, throughout the range

TABLE I.—*Amplitudes of the Harmonic Constituents of the Vowel Sound ō Sung at Various Pitches by the same Voice.*

G G♯ A B♭ B c c♯ d e♭ e f f♯ g g♯ a b♭ b c' c♯' d' e♭' e' f' f♯' g' g♯' a' b♭' b' c'' c♯'' d'' e♭'' e'' f'' f♯'' g'' g♯'' a'' b♭'' b'' c''' c♯''' d''' e♭''' e''' f''' f♯''' g''' g♯''' a''' b♭''' b''' c^{iv}

from *f'* to *g* the first and second partials are the main components; from *f* to *d* the third partial is prominent, and about *c* the fourth partial becomes strong. At G, in one voice, the fifth partial was strong, whereas in the example now given it was weak.

When the several voices were compared in respect of the relative strength of the partials, it became clear that this relative strength might vary greatly without affecting the vowel quality much.

This is brought out by Table II., which contains the constituents of *ō* as sung by five different voices on five different notes. The figures are proportional to the actual amplitudes of each harmonic constituent, and therefore not only show the relative value of each constituent in a given vowel, but also indicate (although only very roughly) the strength of the several voices on each note. Those constituents which are most considerable are printed in large type. Those printed in small type may perhaps be regarded as accidental and not essential to the vowel sound.

On *e'* the vowel sound is composed of the two first partials, but with different voices these were present in proportions which varied from $\frac{100}{102}$ to $\frac{100}{34}$.

On *c'* the vowel sound was still composed almost wholly of the two first partials, and with different voices these were present in proportions which varied from $\frac{100}{145}$ to $\frac{100}{46}$. From this it is evident that the vowel sound may vary very slightly as a vowel when the proportions of its constituents vary largely. No doubt it may be said that the vowels pronounced were different vowels, but it must be remembered that each man was at least trying to sing the same vowel and was controlled by the same observers, who were satisfied that he did sing generically the same vowel.

On the other hand, the quality of the voices was extremely different. Voice No. 1 was a fine, powerful, trained baritone. No. 2 was a high-pitched voice with no notes below *f*, rather harsh, and unaccustomed to singing. No. 3 was the trained bass voice of a man of eighty. Nos. 4 and 5 were voices of average range and moderate power, with some musical training. No. 6 was a powerful bass. The differences in the proportions of the constituents appear to us therefore to indicate differences in the quality of the voices rather than differences in the vowel.

On *c'* the two first partials give a good *ō*, whether the second is one and a half times as big as the prime or the prime twice as big as the second.

The results on *a* and *b* do not differ much from those on *c'*; when, however, we come to *g*, the table shows us that while two out of the five voices formed their *ō* by producing two partials as in the case of the higher notes, three other voices introduced a considerable third partial. On descending one tone lower, to *f*, we find that all the voices agree in employing a strong third partial. This third partial is sometimes less than half the prime, but it is never so small as one-third, and in one case it is sensibly larger than the prime. It would also be observed that it was the voice No. 5, which had no sensible third on *g* which gave the largest third on *f*. It should also be noted that the smallest third is due to voice No. 4, which was at the end of its range, and spoke or sang half a tone sharp.

As we descend below *f* the third assumes more and more prominence; on *d* voices 1 and 5 gave the following series of partials:—

	I.	II.	III.	IV.	V.	VI.
1°	4·4	13·4	8·2	1·6	2·2	1·0
5°	3·3	7·2	5·6	0·5	0·7	0·2

Table II. shows that by the time B is reached the fourth partial has become very prominent.

NOTE.—The analyses put within brackets are a semitone different in pitch from the others in the group, and have their pitch marked at the side. They have been taken where there did not happen to be an example on the exact pitch wanted.

On G voice 1 gave the following series :—

1° 1·3 0 1·5 4·0 0·8 0·4,

On F another voice (No. 6) gave

6° 2·2 1·0 1·5 0·8 3·4 0·1.

In this last example we see that the fifth partial was much greater than the prime.

For the sake of brevity we have only given a few cases. Our results contain the analyses of more than a hundred curves, from which we have given what we think fairly representative examples. Moreover, the curves analysed were in many instances chosen from numerous examples, so as to represent not one experiment, but several. We will now state the results arrived at in somewhat more general terms.

1. At those pitches commonly employed in conversation the sound $\bar{o}$ consists essentially of the first two partials of the note employed. The proportions between these partials may vary between 1 : 1·5 and 1 : 0·5; perhaps even more widely. When curves obtained by speaking were compared with those obtained by singing the proportions were much more nearly alike than could have been expected. The spoken $\bar{o}$ differed chiefly from the singing $\bar{o}$ by a continuous change of pitch, and also by running into an $\bar{u}$ towards the end of the utterance.

2. When $\bar{o}$ is sung from g downwards the third, fourth, and fifth partials appear in succession in such a way as to keep that which is the highest prominent partial not far from $b'\flat$, which is called by Helmholtz the characteristic tone of $\bar{o}$. Above g the second and strongly reinforced partial lies in a region varying from three semitones below $b'\flat$ to six semitones above it.

3. Until we reach the lowest notes G and A all the partials between the prime and the highest prominent partial are more or less reinforced. Thus $\bar{o}$ successively consists of the first *two* partials, the first *three* partials, and the first *four* partials. On very low notes we have insufficient data for very positive conclusions, but the second partial seems to sink into insignificance as the fifth comes in.

4. The appearance of new partials as we descend the scale is in some cases and with some voices gradual; in other cases it is singularly abrupt.

Wave-form of ō Sung by the same Voice at Various Pitches.

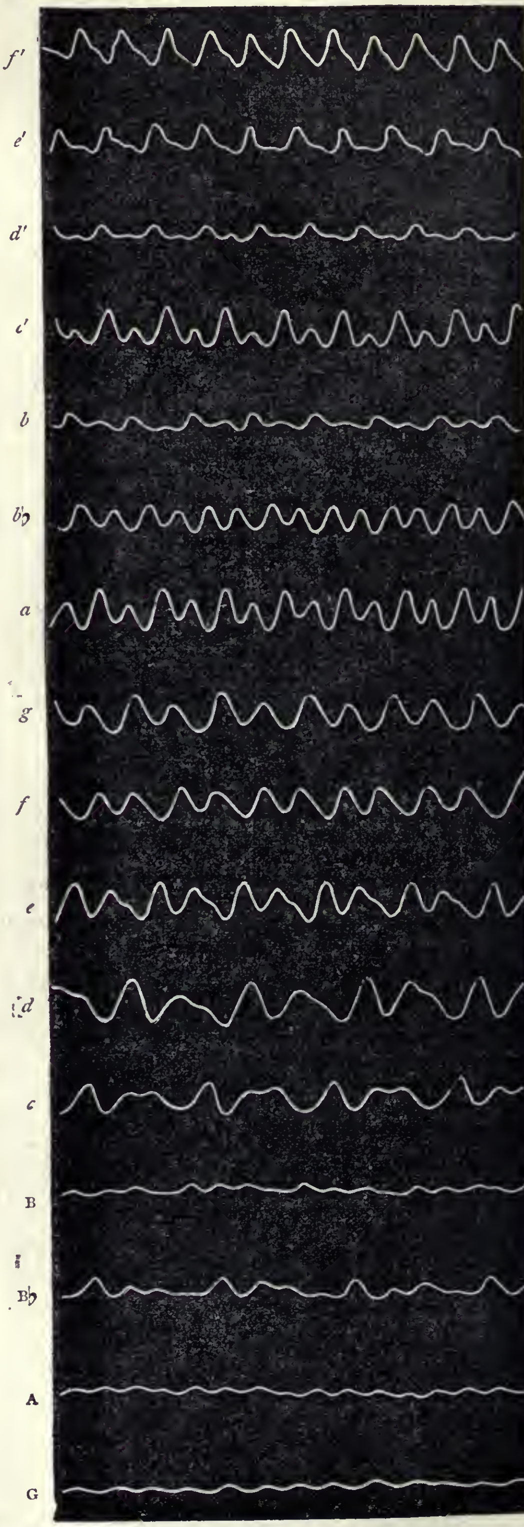

FIG. 1.

This is shown by Tables III. and IV., which give the actual

amplitudes of the third and fourth partials for voices 1, 3, and 5 at various pitches. The place where a somewhat sudden change happens is marked by a vertical bar.

TABLE III.—*Third Partials.*

Pitch of third partial.	*g''*	*f''*♯	*f''*	*e''*	*d''*	*c''*	*b'*	*a'*	*g'*	*f'*♯	*f'*	*e'*
Voice 1	1·5	1·5	1·3	2·5	2·7	4·5	7·3	8·2	6·1	2·8	6·1	1·1
„ 3	0·1	0·2	—	0·4	0·2	1·1	│3·5	—	4·6	2·9	2·5	3·5
„ 5	0·5	0·2	1·3	1·0	0·3	│5·8	6·4	5·6	—	2·3	1·5	2·2

TABLE IV.—*Fourth Partials.*

Pitch of fourth partial.	*c'''*	*b''*	*b''*♭	*a''*	*g''*	*f''*	*e''*	*d''*	*c''*	*b'*	*b'*♭	*a'*
Voice 1	1·0	1·4	0·8	2·2	0·6	0·4	0·7	1·6	3·3	3·1	4·7	2·9
„ 3	0·4	0·4	—	0·4	0·2	0·3	0·5	—	│3·5	2·8	3·6	3·9
„ 5	0·3	1·4	0·7	0·8	0·6	1·3	1·3	0·5	—	│2·5	1·5	2·1

It will be seen that the third partial springs into prominence more suddenly with voices 3 and 5 than with voice 1, but there is a rapid increase with voice 1, where the sudden change occurs with the other voices. This want of continuity suggests an adjustment or tuning of the mouth cavity, an idea which receives support from experiments on the sound *ū*, to be afterwards described.

Another very marked example of this sudden introduction of a new partial was given by voice 6, a powerful bass.

Note sung	B♭	A	G	│F
Fourth partial ...	7·5	8·0	4·5	│0·8
Fifth partial ...	0·9	1·2	0·9	│3·4

The apparent tuning of the mouth cavity required to produce the sudden introduction of a new partial might perhaps be described as the involuntary selection of a new *ō* of different quality, but better adapted to be sung on the new note. We do not reject this mode of considering the phenomenon, but at the same time point out that there is a generic property common to the *ō*'s above and below the critical notes which leads us to regard all the varieties as sensibly one and the same vowel sound. Our experiments do not so far show whether any tuning takes place in the upper part of the scale, where nothing but a prime and its octave are present.

5. Whenever a partial falls on *b'*♭ we find that it is specially prominent. This fact was ascertained by Helmholtz; and the confirmation of his experiments by a completely different method is very satisfactory, both as showing that the letter *ō*, as pronounced by the English and German singers, did not differ sensibly, and as tending to justify our confidence in the method of investigation which we have followed. In that part of the scale where the vowel consists simply of the prime and its octave, the second partial, when it falls on *b'*♭, is usually a maximum, both absolutely and relatively to the prime. This result was to be expected from the experiments of Helmholtz and Donders.

6. The upper partials are often larger in amplitude than the prime.

The second partial was occasionally a little more than double the prime; the third partial in low notes was sometimes four times as great as the prime. The fourth partial was in one case eight times as large as the prime and the fifth partial in our single example on F was one and a half times the prime.

We defer drawing any conclusions from these results until we have described the analogous phenomena observed for the vowel sound *ū*.

FLEEMING JENKIN
J. A. EWING

NOTES

PROF. F. V. HAYDEN has recently been elected Foreign Member of the Royal Academy of Sciences, Rome. This is one of the oldest scientific societies in the world, and the number of foreign members in the department of the natural sciences is only thirty-seven. The University of Rochester (U.S.) at its annual commencement on the 3rd instant, conferred on Dr. Hayden the honorary degree of Doctor of Laws. In his letter communicating its action, the president, Rev. Dr. M. B. Anderson, says:—"The Trustees and Faculty of the University desired to recognise by this action your great services to science through your personal attainments, as well as the almost unparalleled energy and success which have characterised your explorations in regions hitherto unknown to the geologist as such. They did not hope to add in the slightest degree to your well-earned reputation, but they desired to express their appreciation of the honour you have done our country and the state and city of your early residence, by those great labours which have linked your name with geological science for all coming time. The friendship of many years has made my official connection with this public act a source of the most sincere pleasure."

THE Netherlands Zoological Society held its annual summer meeting at Harlingen on July 14 last. The chairman of the Committee for the Zoological Station, Dr. Hubrecht, gave a short statement showing how the prospects of the young institution had considerably improved during the past year, how an annual income of about 150*l*. had been obtained, which had permitted an extension of the wooden building, described and figured in NATURE, as well as the application of a new heated air motor (system Rennes, Utrecht) for oxygenising the sea-water in the aquaria by a constant stream of atmospheric air. The transportable Zoological Station has been erected during the summer months of 1878, on the Island of Terschelling, between the Zuyder and North Seas, and several members of the Society are there now, for the greater part occupied in the study of the invertebrate fauna of the Dutch coast. These investigations are being considerably facilitated by the great liberality of the Marine Minister, who has put a vessel with a mate and three sailors at the entire disposal of the Committee for the next six or eight weeks. As has hitherto been done, it is expected that at the end of the season a circumstantial report will be issued by the Committee, in which the results of this year's campaigning will be duly recorded.

THE death is announced of Dr. Thomas Oldham, who was, from its origination in 1850 till 1876, at the head of the Geological Survey of India. It was under his direction that the official geological survey was commenced, first under the Hon. East India Company and afterwards as part of the Government public service; and until his retirement, from ill-health, he had the control of the issue of the official geological maps, as, portion by portion, the work was completed, and the issue of the memoirs explanatory of the maps. In 1861, eleven years after the survey was commenced, he originated the publication of the folio-sized "Palæontologia Indica," which consisted of plates, with descriptive letter-press, illustrating the fossils of the country, and the work has progressed steadily in fasciculi as an official publication printed by command of the Governor-General of India. Dr. Oldham was born in Dublin in May, 1816, and entered at Trinity College, Dublin, at the age of sixteen. After taking his B.A., he studied in 1837-38 at the engineering school of Edinburgh, and attended Jameson's lectures on geology and mineralogy. Returning to Ireland in 1839, he became chief geological assistant to Major-General Portlock, then at the head of the survey of Ireland, and he helped in the preparation of the well-known report on Londonderry, Tyrone, &c., published in 1843. After being for a while curator and assistant-secretary of the Geological Society of Dublin, he held for a year the professorship of engineering, and in 1845 succeeded the late Prof. John Phillips as Professor of Geology. He was then appointed local director of the geological survey of Ireland, and the Geological Society of Dublin elected him its president. After the various experiences thus gained, in 1850 he was appointed to organise the geological survey of India. There were many unexpected difficulties to

contend with, but during the sixteen years of his office these were more or less overcome. Besides being elected a Fellow of the Royal Society in 1848, he received the Royal medal of the Society in 1875. The Emperor of Austria conferred on him a medal in recognition of his work. The papers he wrote, apart from his official work, were not numerous. He died at Rugby July 17.

IT has been arranged that Prof. McKendrick, as President of the Physiological Section at the meeting of the British Medical Association in Bath, will give an address on the recent progress of acoustics, more especially as regards the mechanism of the ear.

AT a meeting recently held at Netley of the subscribers to the Parkes Memorial Fund, it was resolved—1. That a prize of one hundred pounds in money, and a large gold medal bearing the portrait of the late Dr. Parkes, be given triennially for the best essay on a subject connected with hygiene, to be declared at the commencement of each triennial period, the prize to be open to the medical officers of the army, navy, and Indian services of executive rank on full pay (with the exception of the officers of the Army Medical School during their term of office). 2. That the subject for the first competition for the above-named prize be as follows:—"On the Effects of Hygienic Measures in arresting the Spread of Cholera." 3. That the essays be sent in to the Committee of the Parkes Memorial Fund, care of the Director-General, Army Medical Department, 6, Whitehall Yard, London, S.W., on or before December 31, 1880. Each essay to have a motto, and to be accompanied with a sealed envelope bearing the same motto, and containing the name of the competitor. 4. That a bronze medal (also bearing the portrait of the late Dr. Parkes) be given at the close of each session of the Army Medical School to the best answerer at an examination in hygiene.

AT p. 104 of this volume we called attention to an additional exception to one of Fermat's remarkable statements regarding the forms of primes. The discoverer, M. Pervouchine, has lately succeeded in showing that

$$2^{2^{23}} + 1$$

(a number containing many more than *two millions and a half* of places of figures) is divisible by the prime number

$$167,772,161$$

or

$$5 \cdot 2^{25} + 1.$$

This result has been verified by Zolotareff of the St. Petersburg Academy of Sciences. We are not told what method he employed, but it is obviously reduced to a question of mere labour by the use of the binary scale. And even this labour may be dispensed with by the aid of very simple machinery. It is much more difficult to see how M. Pervouchine was led to choose this divisor, though it would appear that the divisor was probably first assumed and the dividend calculated from it.

THE annual meeting of German Archæologists and Historians will take place at Marburg about the middle of September.

THE American Minister for Agriculture has recently stated that in the extensive caverns of Texas enormous masses of guano are deposited. The quantity is estimated at 20,000 tons, and the quality is said to be superior to that of fish guano. Its origin must be looked for in the immense numbers of bats which inhabit these caverns. It is also reported that in the Indian Ocean several guano islands have been discovered, so that the threatened exhaustion of guano deposits need not be feared for some time to come.

IN different parts of Costa Rica grasshoppers have appeared in alarming masses, particularly near Herodia, Alajuela, and Atenas, one of the most cultivated and fertile districts of the whole country. The coffee crop for this season has been nearly all destroyed by the plague.

AT a recent meeting of the Geneva Society of Physics and Natural History, Prof. Alph. de Candolle presented a glass jar containing fruits of the coffee plant collected before maturity in Mexico, preserved in a liquid which chemical analysis proved to be salt water. It is fifty years since the jar thus filled was hermetically sealed, under the eyes of Aug.-Pyr. de Candolle, and to-day the coffee-beans which it contains are in a thoroughly satisfactory state of preservation. The water contains a solution of chloride of sodium and very small quantities of other chlorides or salts. No gas was found in solution; the water must then have been boiled, and introduced while hot into the jar. This experiment may give valuable hints as to the substitution of salt water for alcohol (of which every one knows the inconvenience) for the preservation of organic substances.

THE Japanese Government have finally authorised the immediate commencement of a line of railway between Kiôtô and Otsu, which is expected to cost nearly a quarter of a million sterling, and will probably be completed in three years. The construction of this line will have a beneficial effect upon that part of the empire, as it will afford a much needed outlet for the valuable products raised at Tsuruga, and in the rich districts in the neighbourhood of Lake Biwa.

THE Government engineering works at Shindin are a conspicuous proof of the enterprise of the Japanese, and it is satisfactory to learn from the Japan papers that the undertaking is in a highly prosperous condition. It was formed by combining the Kaga Foundry, originally started by the Daimio of Kaga in 1869, with the Vulcan Iron Works, which were bought by the government in 1872. The foreign staff at present consists of only four persons, and the works give employment to nearly a thousand skilled mechanics, exclusive of ordinary labourers. In addition to several works which have been recently executed, there are said to be sufficient orders on hand to occupy the staff for the next three years. The evidence which this establishment exhibits of the rapid development of internal trade is very satisfactory to all who watch with interest the progress of Japan.

"NOMENCLATOR STRATIGRAPHICUS: a Hand-book of the Nomenclature of the Sedimentary Rocks," by G. A. Lebour, F.G.S., is the title of a work which has been in hand for several years, consisting of a list—as complete as may be—of the subdivisions of the geological scale now or at any time in use in this country or abroad. The names are arranged in alphabetical order as the easiest for reference. The date of publication, the meaning when it seemed necessary, and the equivalence, are also given. The volume will be of at least 250 pp., and will be published as soon as the number of subscribers has reached 200. Information may be obtained from Mr. G. A. Lebour, 2, Woodhouse Terrace, Gateshead-on-Tyne.

THERE are very few botanical gardens, colonial or foreign, that can boast of such a carefully-prepared or extensive catalogue as that which Dr. Schomburgk has pronuced of the plants under cultivation in the Government Botanic Garden, Adelaide, South Australia, now before us. It comprises 285 pages; and not alone on the score of bulk, but also with regard to its contents, it is something more than a mere catalogue. The plants are arranged under their natural orders, the scientific and common names and native countries being given also. We are told whether the plant is a tree or shrub, a climber, a trailing, or a creeping plant, annual, biennial, or perennial, evergreen or deciduous, out-door or stove-plant. Besides all this are too good indices, one of English and the other of Latin names. From the preface a very good idea may be had of the climate and meteor-

ology of Adelaide, as well as of the behaviour of introduced plants from various parts of the world. The sudden changes of temperature during the Australian summer months of December, January, and February, are often very injurious to vegetation. The lengthened period of eight or ten weeks without a drop of rain, which is not uncommon, has a serious effect upon both indigenous and acclimatised plants. In the months of March, April, and May, when our own deciduous trees are putting on their fresh green foliage, the same identical European plants which have established themselves in their Australian home are assuming their autumnal tints and dropping. Alpine and tropical plants suffer in South Australia not only from the dry atmosphere, but—the tropical ones especially—from the cold of the winter months. On the other hand, the extreme heat in the month of January, coupled with the hot north wind, literally bakes the fruits upon the trees. At three o'clock in the afternoon of the 10th of January last, it is stated that the thermometer in the Botanic Garden registered 116° in the shade and 166° in the sun. The catalogue is illustrated by seventeen full-page views in the garden, engraved from photographs.

WE have before us quite a pile of *Reports* and *Proceedings* of provincial societies, all of which, we may say, appear to be in a prosperous and healthy condition. We can do little more than give the names of the societies which have issued these reports. As usual, the *Natural History Transactions* of Northumberland, Durham, and Newcastle-on-Tyne contain some papers of great importance. A paper on Eggs, by Dr. Embleton, and one on Roman remains at South Shields, by the Rev. Dr. Hooppell, deserve special mention; there are also some interesting Bewick letters. The preface to the *Report* of the Rugby School Society is rather desponding, but the contents are really creditable to the contributors, and we are glad to see the attendance is generally very good; in the Report on the Temple Observatory, a description and plan of the new buildings is given. The eighth Report of the Wellington College Society shows it to be in a state of vigorous activity, all the departments adding largely to their collections; an ethnological department has been set on foot. Besides the above we have received the *Proceedings* of the Belfast Natural History and Philosophical Society; the *Report and Proceedings* of the Manchester Field Naturalists and Archæologists; *Proceedings* of the Birmingham Philosophical Society; *Eighth Annual Report* of the Leeds Naturalists' Club; *Annual Report and Transactions* of the Plymouth Institute and Devon and Cornwall Natural History Society; *Proceedings* of the Liverpool Naturalists' Field Club; *Seventh Report* of the Croydon Microscopical Club; *Report* of the Northampton Natural History Society and Field Club; and the *Eighth Annual Report* on the Devon and Exeter Albert Memorial Museum, &c. Several of these publications contain really important papers which deserve a wider circulation than they are likely to receive in their present form. In this connection we may mention an interesting tractate published at the *Advertiser* office, Wilmston, containing an account of some Lancashire Artisan Naturalists, by Mr. A. A. Reade. From abroad we have received the *Papers and Proceedings* of the Royal Society of Tasmania; *Proceedings* of the Linnean Society of New South Wales; *Report* of the Auckland Institute; *Report* of the Dunedin Naturalists' Field Club, and the *Bulletin* of the Essex (U.S.) Institute.

THE temperature of flames has been investigated by Signor F. Rosetti (*Istituto Veneto*, ser. v. vol. iv.) in a very thorough manner by means of his ingenious calorimeter. The maximum temperature of a Bunsen flame is found to be 1,360° C., and results from a combustion of 1 volume of gas and $2\frac{1}{2}$ volumes of air. The admission of a greater or less quantity of air reduces the temperature. Changes in pressure have but slight influence on the temperature. The flame given by gas diluted with the same volume of nitrogen shows a temperature of 1,180°, and diluted with 3 volumes of nitrogen, 1,040°. The same degrees of dilution with carbonic acid show respectively 1,100° and 780°. Among other temperatures noted were the following:—

	°
Locatelli lamp	920
Stearine candle	940
Petroleum lamp with chimney	1,030
The same without chimney—	
Illuminating part	920
Sooty envelope	780
Alcohol lamp (alcohol 0·912)	1,170
Ditto (alcohol 0·822)	1,180

The slight difference in heating power resulting from widely-varying percentages of water in the alcohol is worthy of remark.

THE medical students of Paris have not forgotten that Rousseau was a botanist as well as a philosopher, and sent a delegation on July 2 to Ermenonville to celebrate the 100th anniversary of his death. Three addresses were delivered in the name of the medical body—one by Dr. Bergeron, the toxicologist, the second by M. de Lannessau, and the third by M. Baillon, himself a botanist and a professor of the School of Medicine. The speakers referred in eloquent terms to the love of Rousseau for nature, his observational genius, and his works on botany. The students had prepared a splendid crown made of *pervenches* (periwinkle, *Vinca*) the flower which Rousseau loved best, and which had been collected by them in the very forest where the philosopher spent his last years. As no boat was to be had to reach the island where the author of the "Nouvelle Héloïse" is buried, one of the students threw himself into the water and swam with the testimonial to the spot sacred to the memory of the impulsive Frenchman.

H. J. RINK has recently laid before the Dutch Academy of Sciences an elaborate paper on the alterations caused by changes of temperature in the resistance offered by mercury to the passage of the galvanic current. The coefficients found hitherto range between 0·00086 and 0·00104. The author has made experiments with seven tubes of mercury, each a metre in length, and after making all corrections for expansion of glass, &c., obtained the number 0·000989 as the coefficient for the change in the resistance corresponding to an alteration of a degree Celsius. He finds, furthermore, that the resistance increases in a more rapid ratio than the temperature.

THE great Giffard captive balloon is in the hands of a Commission appointed by the Prefect of the Seine, and composed of M. Troost, Professor of Physics at the Sorbonne, Capt. Renard, head of the balloon service of the War Office, and a few others. The Commission was appointed on July 19, and on the 20th paid its first visit to the balloon, which is attracting public notice to an unprecedented degree. Thousands of spectators look through the railings of the Cour du Carrousel at the stupendous sphere which is ready to start for its elevated station. On the 20th the wind was very violent, and no ascent was tried. The balloon will not be opened to the public before the Commission has rendered its report. A second visit took place on the 21st, when a successful trial ascent was made. A M. Carrol has designed and made wings for directing an elongated balloon. A man will be suspended under it by a rope and will try to direct it. This kind of experiment has been tried at Paris twice—by Deghen, a Viennese clockmaker, about seventy years ago, who failed; and a year ago at la Villette gasworks, by a policeman, who obtained no result. M. de Fonvielle writes that he visited the Carrol flying machine which is yet imperfect, but may eventually work. The balloon will be inflated with hydrogen gas, and the

man engaged to work the wings is an acrobat of effective muscular power. The experiment will very likely take place at Enghien, on the lake, where the balloon will be retained by a small floating buoy.

We have received a "Catalogue des Ouvrages d'Astronomie et de Météorologie," found in the principal libraries of Belgium, prepared at the Royal Observatory of Brussels. It extends to upwards of 630 pages, and will be found of great service to those interested in astronomy and meteorology. The publisher is Hayez, of Brussels.

In our report last week (p. 323) of the Physical Society meeting of June 22, in Mr. W. Baily's paper, the expression A cos θ should be A cos 2θ, so that the equation to the ellipse of polarisation would be

$$1 + A\cos 2\theta + B\sin 2\theta = r^{-2}\{1 - (A^2 + B^2)\}$$

The author of the paper on Complementary Colours was Mr. John Gorham, not Graham.

The additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. Enoch; a Rhesus Monkey (*Macacus erythrœus*) from India, presented by Miss Davis; a Cape Zorilla (*Ichonyx zorilla*) from Africa, presented by Mrs. J. J. Monteiro; a Common Cuckoo (*Cuculus canorus*), European, presented by Mr. G. D. Careless; three Alligator Terrapins (*Chelydra serpentina*) from North America, presented by Mr. J. H. Thompson, C.M.Z.S.; a Chimpanzee (*Troglodytes niger*) from West Africa, a Golden-headed Marmoset (*Midas chrysomelas*) from Para, two Egyptian Flamingos (*Phœnicopterus antiquorum*) from North Africa, deposited; an Eland (*Oreas canna*) born, five Amherst Pheasants (*Thaumalea amherstiæ*), an Argus Pheasant (*Argus giganteus*) bred in the Gardens.

JOSEPH BLACK[1]

The study of the history of a science is of great importance not only from a psychological point of view, but also as throwing light on the present position of the science. In science, as in other natural products which have *grown*, we find survivals which can only be understood when the development is known. Such historical studies may very conveniently be associated with the biographies of the great scientific leaders under whom progress has been made, and whose individual mental peculiarities have left permanent impressions. I intend on this occasion to direct your attention to the life and work of Dr. Joseph Black both because he was one of the first to give to chemistry the direction which it still preserves, and because his life is of special interest to us as Edinburgh students of chemistry.

Joseph Black was born at Bordeaux, in 1728. His father, John Black, was a native of Belfast, a member of a Scottish family settled in Ireland. His mother belonged to the family of Gordon, of Halhead, in Aberdeenshire, and was a cousin of Dr. Adam Ferguson. In 1740 he was sent home and educated at the Grammar School of Belfast. In 1746 he matriculated at the University of Glasgow, where he remained till 1750, studying in the faculties of arts and medicine. He then removed to Edinburgh, where he graduated as doctor of medicine in 1754. In 1756 he was appointed Professor of Anatomy and Lecturer on Chemistry in the University of Glasgow. He soon exchanged with a colleague the duty of teaching anatomy for that of physiology, and continued to lecture on physiology and chemistry till 1766, when he was called to Edinburgh to succeed his friend and teacher, Dr. Cullen, in the Chair of Chemistry. He died November 26, 1799. Such is a brief sketch of his quiet and uneventful life. His contemporaries Dr. Robison and Dr. Adam Ferguson, give us some account of his manner of life and study. He was minutely accurate and careful in everything he did, and this punctiliousness and his feeble health account for the small *quantity* of work of which he has left a record. As a student he is said to have kept two sets of note-books; into one he entered observations, experiments, hints of experiments, extracts from the works of others, in fact all the miscellaneous additions to his knowledge. These he afterwards transcribed into the other set, arranging them in order of subjects. "In short," to quote Dr. Robison, "he kept a journal and ledger of his studies and posted his books like a merchant." It has occurred to me that possibly this mention of Dr. Black's business-like habit may have been present to the mind of Sir Walter Scott when describing the interview of Francis Osbaldistone on his return from Bordeaux, with his father. "—but what have we here? 'Bordeaux founded, castle of the Trompette, palace of Galienus,'—well, well, that's very right, too. This is a kind of waste book, Owen, in which all the transactions of the day, emptions, orders, payments, receipts, acceptances, drafts, commissions, and advices are entered miscellaneously." "That they may be regularly transferred to the day-book and ledger," answered Owen; "I am glad Mr. Francis is so methodical."

His style as a lecturer is well described by Dr. Robison:—

"He endeavoured every year to make his courses more plain and familiar, illustrating them by a greater variety of examples in the way of experiment. No man could perform these more neatly and successfully. They were always ingeniously and judiciously contrived, clearly establishing the point in view, and never more than sufficed for this purpose. While he scorned the quackery of a showman, the simplicity, neatness, and elegance with which they were performed were truly admirable . . . his students were not only instructed, but (they knew not how) delighted; and without any effort to please, but solely by the natural emanation of a gentle and elegant mind, co-operating, indeed, with a most perspicuous exhibition of his sentiments, Dr. Black became a favourite lecturer." His private life was one of unvaried regularity and order, and was brought to a fit close by his death, which is thus described by Dr. Adam Ferguson.

"His own constitution never was robust, and every cold, or any approach to repletion, affected his breast so much as to occasion a spitting of blood. This he guarded against by restricting himself to a moderate or abstemious diet. As his infirmities increased with age, he met them with a proportionate attention and care, regulating his food and exercise by the measure of his strength; and thus preventing the access of disease from abroad, he enjoyed a health, which was feeble but uninterrupted, and a mind undisturbed in the calm and cheerful use of his faculties. A life so prolonged had the advantage of present ease, and the prospect, when the just period should arrive, of a calm dissolution. This accordingly followed on the 26th of November, 1799, and in the seventy-first year of his age, without any convulsion, shock, agitation, or stupor, to announce or retard the approach of death. Being at table with his usual fare—some bread, a few prunes, and a measured quantity of milk diluted with water, and having the cup in his hand when the last stroke of his pulse was to be given, he appeared to have set it down on his knees, which were joined together, and in this action expired, without spilling a drop, as if an experiment had been purposely made, to evince the facility with which he departed. So ended a life which had passed in the most correct application of reason and good sense to all the objects of pursuit which Providence had prescribed in his lot." . . . "He had long enjoyed the tender and affectionate regard of parents whom he loved, honoured, and revered, with the delightful

[1] Abstract of Lecture to the Edinburgh University Chemical Society, by Prof. Crum Brown, F.R.S.

consciousness of being a dutiful son; one of a family remarkable for sweetness of disposition and manners, he had lived with his brothers and sisters in terms of mutual love and attachment. He had never lost a friend but by the stroke of mortality, and he felt himself worthy of that constancy of regard. He had followed a profession altogether to his taste, and had followed it in a manner, and with a success which procured him the esteem and respect of all competent judges, and set his name among the most eminent, and he was conscious that his reputation was not unmerited; and with a success, in respect of emolument, which secured the respect even of the ignorant; which gave him the command of every rational gratification, and enabled him to add greatly to the comforts of the numerous descendants of his worthy parents—heirs not only of their name, but likewise of their unambitious moderation and amiable simplicity of character."

Such was Dr. Black as described by those who knew him intimately. We at a greater distance from him can, perhaps, more accurately estimate the character and value of his work. This may be considered under the heads of his three great discoveries. 1. The nature of the difference between the mild and the caustic alkalies; 2. The latent heat of liquids; 3. The latent heat of vapours.

As a student of medicine in this University his attention was early drawn to the chemical characters of caustic potash and caustic soda, the merits of which as remedies in cases of urinary calculus were then much discussed.

Two kinds of alkalies, the caustic and the mild, had long been distinguished. The former act in a burning, caustic, destructive way on animal and vegetable tissues, the latter do not; the latter effervesce when mixed with acids, the former do not; the former are typified by quick or in slaked lime, the latter by chalk or calcareous earth. Previous to Dr. Black's experiments the difference was thus explained:—When calcareous earth is burnt it becomes quick-lime by taking up from the fire a fiery, caustic matter; some of this is given off as heat when lime is slaked, but some of it remains and gives the causticity by which slaked lime is distinguished from calcareous earth. This causticity is transferred (because the caustic matter is transferred) from the lime to other alkalies. Thus, when slaked lime is mixed with a solution of potashes we obtain caustic potash and the lime becomes mild, is re-transformed into calcareous earth, having parted with its *causticum* to the potash. Similarly when sal ammoniac is heated with calcareous earth we obtain sal volatile; but when we act on sal ammoniac with slaked lime the *causticum* passes from the lime to the volatile alkali and caustic ammonia is produced. In all these cases the caustic matter or *causticum* originally obtained from the fire was believed to be transferred from one alkali to another. The effervescence which occurs when a "mild alkali" is treated with an acid was of course observed, but it was looked upon merely as a symptom of the violent movements caused by the mutual saturation of acid and alkali.

When slaked lime is exposed to the air it gradually returns to the condition of calcareous earth. On the hypothesis stated above, it must therefore gradually give off its *causticum* into the air. Black's first experiment seems to have been an attempt to catch the *causticum* as it escaped. We have no details of these early experiments, but from a note-book which can be shown to be of the date 1752 Dr. Robison extracts the following statement of the result:—"Nothing is given off, the cup rises considerably by absorbing air." Another memorandum occurs a little later: "When I precipitate lime by a common alkali, there is no effervescence. The air quits the alkali for the lime, but it is not lime any longer, but C.C.C. It now effervesces, which good lime will not."

A full account of his experiments and conclusions is contained in his graduation thesis (1754), and in a more extended form in 1756 in "Essays and Observations, Physical and Literary, read before a Society in Edinburgh"—the society which afterwards became the Royal Society of Edinburgh. In this classical paper he shows in the clearest manner that the mild alkalies differ from the caustic by containing in addition a large quantity of "fixed air," a particular kind of gas, which we now know as carbonic acid gas. This gas is given off, causing effervescence when the mild alkali is dissolved in an acid, and the caustic alkali does not effervesce because it does not contain fixed air. Wherever causticity is acquired this fixed air is lost, and *vice versâ*. When slaked lime is mixed with a mild alkali the lime takes the fixed air, and is converted into calcareous earth, while the mild alkali by the loss of fixed air is rendered caustic. In the same way sal ammoniac with calcareous earth gives a mild volatile alkali, the fixed air being transferred from the lime to the ammonia, but with slaked lime a caustic ammonia, because there is here no fixed air to be transferred. The origin of the causticity in the lime is shown to be due to the loss of fixed air which the heat separates from the limestone, and the loss of weight which is observed when limestone is burnt is shown to be exactly accounted for by the loss of the fixed air. Thus Black proved the "causticum" to be *minus* fixed air. Addition or subtraction of the former is really subtraction or addition of the latter, and transference of *causticum* from A to B is really a transference of fixed air from B to A.

It is impossible to look at such a sketch of this part of Black's work without being struck with the resemblance between the theory of causticity which he overthrew, the nature of the truth which he discovered, and the method by which he discovered it, on the one hand, and on the other the theory of Phlogiston, the true nature of combustion, and the method by which it was discovered by Lavoisier; indeed, Lavoisier himself, in a letter to Black, speaks of the new chemistry as "Une carrière que vous avez ouverte, et dans laquelle nous nous regardons tous comme vos disciples."

The discovery of the latent heat of liquefaction and of vaporisation, was made by Dr. Black while professor in Glasgow. I have occupied so much time with the purely chemical part of my subject that I shall only here point out: (1) That Black's determination of the latent heat of water agrees very closely with the most recent results of experiments conducted with all the refinements of modern science; (2) That he studied the fusion and solidification of bodies, such as resin and sealing wax, which pass *gradually* from the liquid to the solid state, or *vice versâ*; and (3) That it was his teaching which induced Watt to commence the series of experiments and speculations which led to the discovery of the dependence of the latent heat of steam upon the temperature, and to the invention of the condensing steam-engine.

A SCHOOL LABORATORY

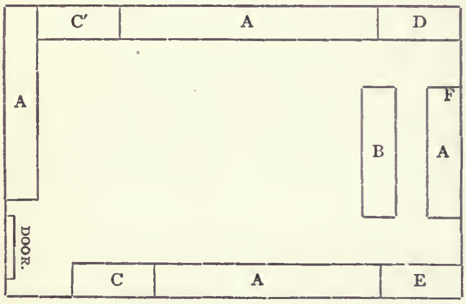
FACTS, not theories. This is the special point in the recent "Head Masters' Report" on science teaching, and, by his interesting account of it in NATURE, vol. xvii. p. 317, Mr. Tuckwell has afforded some opportunity of counting the cost to head-masters projecting a development of their science side, but apparently the Report gives no detail, and it is in this direction, perhaps, that many seek chiefly for information; they would like to know more fully what facilities may be obtained for a particular outlay.

In the hope of giving reliable information of this sort I submit the following particulars:—

The governors of Exeter School, hoping to rekindle the torch of science, lately so unhappily extinguished in the West by the Taunton College authorities, have recently

erected a chemical laboratory; it is intended for temporary use indeed, but affords facilities for school work almost rivalling those of the most costly appliances on Mr. Tuckwell's list, and at an expense not much greater than that of the cheapest; in fact, it has been arranged on a plan based upon experience of the two schools in question. I have said it is intended for temporary use; I do not mean that it is not calculated for a fair term of service; it is temporary because the present location of the school is not a permanent one.

Abutting a stone wall 10 feet high, there is built a room 30 feet by 26 feet, and about 16 feet to the ridge of the roof; it is lighted by skylights on each slope of the roof, and the remainder of the roof is boarded and felted. The building is of timber, floor of wood, and about 9 inches above the ground. The bare building thus described cost 88*l.* The interior arrangements are as shown by the accompanying plan:—



A A A A are working-benches giving accommodation for a class of eighteen or twenty at practical chemistry.

They are of $1\frac{1}{2}$ inch deal, supported on tressels 33 inches above the floor and are 25 inches broad, with an under-bench for holding apparatus, and with three shelves in front of them; these are 6 to 9 inches deep, the lowest hold reagent bottles, the next exercises for analysis, and the top shelves are devoted to lecture apparatus when out of use. They are 14, 30, 48 inches above the bench.

B, a lecture-table; its top is 12 feet long, 27 inches broad, $1\frac{1}{2}$ inch thick, beneath are arranged drawers and shelves; it stands 3 feet above the ground. There are two supplies of gas, one about the centre of the table, fitted with three taps, to which Bunsen burners are attached, another of much larger dimensions, for supplying a combustion furnace, which does double duty, for warming in very cold weather and lecture purposes at other times.

C C' are two slate sinks; C is 39 by 21 inches, and 6 inches deep, with three taps for water; C' is 32 by 21 inches, and 6 inches deep, with two taps; the tops of the sinks are about 2 inches above the level of the working-benches, and a third tap to C' serves to supply the condenser of a still.

D is a fume closet 51 inches long, 23 inches deep, and 64 inches high; it is ventilated by a zinc flue about 6 feet high, under which a jet of gas is burnt when necessary; its doors are 4 feet high and glazed, and the roof slants back from the top of this to the wall.

E is a cupboard 48 inches long, 26 inches deep, 75 inches high, with glass doors; inside are shelves arranged for holding apparatus likely to be damaged by the atmosphere of the laboratory. This and the fume-closet are made fairly substantially of deal and are painted or stained. Except the front, back, and sides of the lecture-table, which also are stained and varnished, all other wood-work is left bare.

Beneath B is another cupboard of plain deal, for chemicals, &c.; it is 33 inches high measuring from the ground.

Gas is supplied to the working benches by 17 jets from a 1-inch pipe, which is carried a few inches above the top of the bench round the room; the lecture-table, and a pendant with four burners for lighting purposes, are supplied by branches from this, and a third branch supplies the fume-closet.

There is a water-tap at F for lecture purposes, but no sink.

The cost of these fittings is as follows:—For gas and water fittings (the gas meter is a hired one), 21*l.* 14*s.* 7*d.*; for woodwork and sinks without water fittings, 51*l.* 3*s.* 3*d.* They are all fairly substantially made, as it is intended to move them to the laboratory to be built at the new school. This sum includes lecturer's desk and stool, waste boxes, &c. &c.

The apparatus and chemicals include a Ruhmkorff coil by Apps, giving $\frac{3}{4}$in. spark, combustion furnace, automatic copper-still, 8 lbs. mercury with suitable vessel for keeping it dry and pure under oil of vitriol, Becker's balance turning to $\frac{1}{10}$ grain, ozone generator, Bunsen's cells, fourteen doz. stoppered reagent bottles, about six or eight doz. bottles for holding solids and solutions for analysis, two doz. 5-pint stoppered bottles for holding stocks of solutions, blowpipe with Fletcher's bellows, a supply of Bunsen's burners, test-tubes, racks, chemicals, and all the other indispensables of a laboratory.

These cost, including carriage by rail, &c., somewhat under 47*l.*, which sum will serve for our wants during the first six months' work.

The total cost amounts to 207*l.* 17*s.* 10*d.*, to which we add about 10*l.*, not more, for some office expenses. For this sum we have a combined laboratory and lecture-room, which is calculated to be sufficiently capacious to afford instruction in theoretical chemistry to 70 per cent. of a school of 150 or 160 boys, and in practical chemistry to about 25 per cent. of the same number; also to serve as an occasional class-room for another science subject.

There is nothing handsome about this laboratory; externally it is tarred, and in summer it will be white-washed; inside it is chiefly innocent of paint, and its walls are unplaned; but for real work there is very little wanting.

W. A. SHENSTONE

A NEW DEEP-SEA THERMOMETER

THE most efficient deep-sea thermometer constructed up to the present has been the one known as Six's thermometer, with the bulb protected from pressure, as invented by Messrs. Negretti and Zambra, and described in NATURE, vol. ix. p. 387. This instrument has been extensively used by the expeditions sent out by various governments and scientific societies.

The disadvantages in the old instrument were the following:—1. The indices were, to a certain extent, unreliable, as, however carefully fitted, they were apt to slip down through their own weight, so that the observations were always more or less doubtful; 2. Its accuracy, even in its most perfect condition, did not attain to fractions of a degree, the closest readings differing at least half a degree; 3. The instrument had always to be carried in a vertical position, or it would become considerably deranged. As long as it was sufficient to obtain temperatures varying not less than a degree from one another the old instrument answered tolerably well in deep seas. Recently, however, the bottom temperatures of shallow seas and rivers have come under investigation, and for that purpose the instrument proved unsuitable.

The difference between the temperature at the surface of the sea and that at the depth of a few fathoms does not amount to a whole degree, as a rule, but only to fractions of a degree; hence the observations, to be of any value at all, must be made with an undoubtedly accurate and delicate thermometer. The investigation of the temperatures of the British seas has been urged upon the Government by naturalists and physicists interested in the question of the food supply of the people in its relation to fisheries. The questions of greatest importance were those regarding the influence of temperature upon the habits and migrations of fish, and the determination of the best seasons and temperatures for the development and capture of the various species. This investigation, commenced with the old instrument, has at present only shown that such instruments are not suffi-

ciently reliable for the purpose; a new, more accurate, and more delicate instrument was therefore a great desideratum, and it seems that Messrs. Negretti and Zambra have now solved this problem in a satisfactory manner.

The construction of the new thermometer will be readily understood by reference to Fig. 3. The bulb is cylindrical, and mercury is the thermometrical fluid. The neck of the bulb is contracted in a peculiar manner at A, and upon the shape and fineness of this contraction the success of the instrument mainly depends. Beyond A the tube is bent and a small catch reservoir is formed at B, for a purpose to be presently explained. At the end of the tube a small receptacle C is provided. When the instrument is held bulb downwards it is seen to contain sufficient mercury to fill the bulb, tube, and a part of the reservoir C, leaving sufficient space in C for the expansion of the mercury when the temperature rises. In this position no scale would be possible, as the apparent movement of the mercury would be confined to the space C. When the thermometer is held bulb upwards the mercury breaks off at A, but by its own weight flows down the tube, filling C and a portion of the tube above C, this portion being in proportion to the existing temperature. The scale accordingly is divided from C upwards. To prepare the instrument for observation it is only necessary to place it bulb downwards, the mercury of course assuming the temperature surrounding the instrument in the same way as any ordinary thermometer. When at any time or at any place it is required to read off the temperature, all that has to be done is to turn the thermometer bulb upwards, and to keep it in that position until the reading has been taken. This may be done at any time afterwards: for the quantity of mercury in the lower part of the stem which records the reading is too small to be appreciably influenced by a change of temperature, unless it be very considerable, while that in the bulb will continue to contract with greater cold and to expand with greater heat; and in the latter case some mercury will pass the contraction A and may fall down and lodge at B, but it cannot go further as long as the bulb remains upwards; and thus the quantity recording the temperature in the stem will remain unaltered. It is seen, therefore, that this new instrument is simply a recording thermometer, which accurately and delicately records the temperature at the time and place when and where it is turned over. It is not intended and cannot be used as a self-registering maximum or minimum thermometer.

Of course some contrivance must be provided for turning the thermometer bulb upwards at any depth in the water. For this purpose the instrument is fitted into a wooden frame loaded with shot, free to move from end to end of it, and with its weight so regulated as to render the whole just buoyant in sea-water.

In using the thermometer a cord is passed through the hole in the frame *nearest* the bulb, and the instrument is fastened by this cord to the sounding-line. In descending, the thermometer will be pulled down with the bulb downwards; but upon being pulled up, the instrument, owing to the resistance offered by the water, will turn over and come up bulb uppermost; the temperature of the spot where it turned over will then be indicated. The illustrations we subjoin will further elucidate this matter.

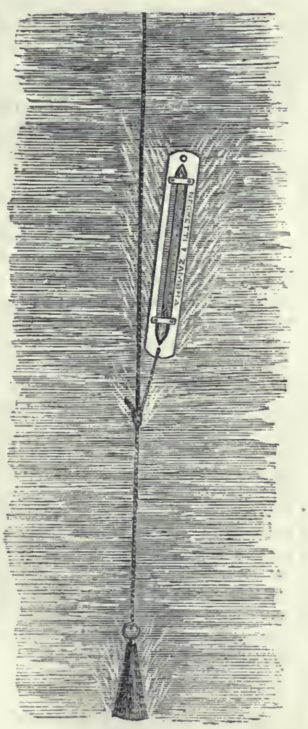


FIG. 1.—Descending.

FIG. 3.

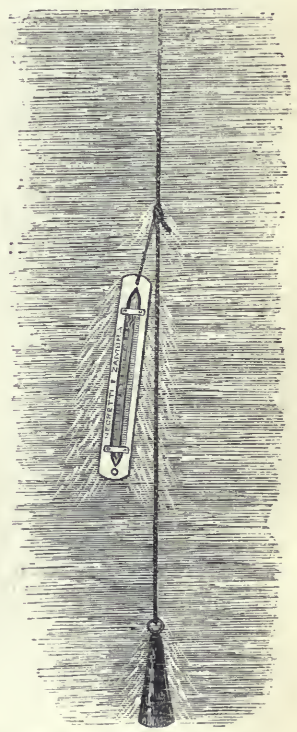

FIG. 2.—Ascending.

As regards the thermometer itself, it was necessary, in order to make it perfectly accurate, to protect it against pressure, even if intended for shallow seas, as well as for the deepest. For whether used in deep or shallow water, unless so protected, its indications would always be more or less faulty. Like an ordinary thermometer, it is devoid of air, and thus differs materially from Six's, which, containing compressed air, has a certain internal power of resistance. Hence the new instrument would be more affected by pressure than Six's, however thick the glass of the bulb. By the simple expedient of placing the entire thermometer into a glass shield or sheath, and hermetically sealing the latter, the effect of external pressure is entirely eliminated. The shield must of course be a strong one. It need not be exhausted of air. Its effect, however, will undoubtedly be to render the thermometer it protects against pressure less sensitive towards changes of temperature; in other words, it will make it sluggish. To counteract this sluggishness, some mercury is introduced into that portion of the shield which surrounds the bulb, and is confined there by means of a partition cemented in the shield round the neck of the thermometer bulb. The action of this mercury is that of a heat-conductor from the exterior of the shield to the interior of the thermometer, and the efficacy of this arrangement has been proved by experiment, the instrument thus protected being, in fact, far superior in sensitiveness to Six's thermometer.

As long as the shield withstands the pressure, the thermometer will be unaffected, and there is abundant evidence already to show that a shield of the above description will resist the pressure even at the bottom of the deepest ocean; doubtless it will be compressed a little at great depths, but the pressure will fail to have any appreciable effect upon the thermometer itself. This method of shielding is quite efficient, and thermometers thus protected need not be tested for pressure in the hydraulic press; all that is necessary is to test them very accurately for sensitiveness and for errors of graduation. The new instrument is intended to be a standard instrument and permits the reading off of at least two-tenths or even one-tenth of a degree. The test for sensitiveness determines how many seconds the instrument requires to note a change of 5° rise or fall, and the time has been found to be from five to ten seconds.

A considerable number of these instruments have already been tested at Kew Observatory with perfectly satisfactory results, which place beyond doubt their value as standard deep-sea thermometers.

Thus, provided the turning-over gear is found to answer, this

new instrument evidently possesses great advantages. It has no scale attached to it, the graduation and figures being distinctly marked on the stem itself, and the shield effectually preserves them from obliteration by sea-water. The back part of the stem is enamelled white, rendering the graduation and column of mercury extremely distinct.

When the instrument is immersed in the water the descending line may be stopped or checked any number of times, and it is of course quite immaterial in what position the instrument enters the water; the illustrations show at a glance that it will infallibly assume the position "bulb downwards" when descending rapidly, and all that is needed is that care should be taken in the pulling upwards. The first pull in this direction should be quick and sudden and be continued for some little time; at the same time the pulling upwards must be continuous, since stoppages would invalidate the readings.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

A MEETING of the members of the Yorkshire College of Science was held on Monday at Leeds. A sum of 56,000*l*. has now been promised in donations, and the endowments from the Akroyd Foundation, the Clothworkers' Company, and the bequest of the late Mr. Brown would, if capitalised, represent a further sum of about 20,000*l*. On the question of the proposed new university the committee reported that the college had held friendly communications with the authorities of Owens College, but could not at present make them the subject of a public report. Mr. Baines stated that the number of students this year was 355, as compared with 288 last year.

We have received a calendar of the Newcastle College of Physical Science, which contains full information concerning the curriculum at that institution, examination papers, scholarships, &c.

SCIENTIFIC SERIALS

Bulletin de l'Académie Royale de Belgique, No. 4, 1878.—In a further paper on the scintillation of stars, M. Montigny here deals with the changes of colour in stars of red and orange tints. From a table giving the general averages of relative frequency of the seven colours in such stars, it appears that the relative frequency of red much exceeds that of any of the other colours, whether in rainy or dry weather; that red, green, and especially orange, are in much greater proportion in dry than in rainy weather; while on the other hand, the frequency of blue and yellow is more marked under the influence of rain. Taking Pollux and Capella as samples of yellow stars, M. Montigny found in them the frequency of red and especially of yellow was much increased, while the proportion of orange was notably diminished. The proportion of blue was the same as in stars of the other type.—M. Masquelin contributes a valuable paper on the development of the inferior maxillar in man, in which he establishes the concurrence of the two modes of ossification in one bone, viz., that by the direct or metaplastic process, and that by the indirect or osteoblastic. It would thus appear that the histological process of ossification cannot serve to determine the morphological value of a bone.—A paper on oscillations of the Belgian coast, by M. Van Rysselberghe, aims at proving a sinking of the coast at Ostend, but the validity of the evidence is doubted by the reporters.—An interesting report on Daltonism in relation to railway-working is presented by M. Delbœuf.—M. Fraipont has a fourth and concluding article on the Acetinians of the Ostend coast, and Dr. Woodward records the discovery of a species of Brachyour crustacean in the coal formation near Mons (to which his attention was called by M. de Koninck).—The theory of the telephone is the subject of a note by MM. Navez.

Journal de Physique, May, 1878.—A new spectroscope here described by M. Thollon offers several advantages; it is direct vision and of perfect symmetry, and can be easily adapted to astronomical telescopes; the prisms (movable) are worked by a rigorously geometrical process, so that a ray coming along the axis of the collimator reaches the axis of the telescope only after twice traversing the whole system of prisms with the minimum of deviation; a considerable dispersive power may be had and may be widely modified in the same instrument; lastly, it affords very exact spectrometric measurements.—Some experiments in which the electro-magnetic rotation of liquids is illustrated with acidulated water containing a little lycopodium powder, the effect being projected by means of Duboscq's new apparatus, are described by M. Bertin. M. Gernez has a note on the production of different hydrates in concentrated supersaturated solutions under the influence of a mechanical action (rubbing the walls of the vessel with a rigid rod).—The metallic reflection of polarised obscure calorific rays is studied by M. Mouton.

Reale Istituto Lombardo di Scienze è Lettere, Rendiconti, vol. xi. fasc. vii.—We note the following papers in this number:—Jealous insanity, by M. Verga.—Expression of pain according to sex, age, individual constitution, and race, by M. Mantegazza.—Contributions to the study of the Italian chiroptera, by M. Regalia.—On the cranium of Volta, by M. Lombrosi.—Examination of the observations made by the committee appointed to adjudicate a prize on the theme, "Programme of a Hospital for Contagious Diseases, suited to the City of Milan," by M. Zucchi.—Study on the prevalent diseases of the vine, by MM. Garovaglio and Cattaneo.

Vol. xi., fasc. viii., ix.—In these numbers we note the following:—On dominant diseases of vines, by MM. Garovaglio and Cattaneo.—Studies on the albumen of milk and on the origin of buttermilk curd, by MM. Musso and Menozzi.—On the causes and circumstances affecting hereditary transmission in animals, by M. Lemoigne.—Observations on elephantiasis in the Arabs in the environs of the Ticinese district, by M. Sangalli.—The third molar in the human race, by M. Mantegazza.—On the distribution and termination of nerves in the tendons of man and other vertebrata, by M. Golgi.

Zeitschrift für wissenschaftliche Zoologie, vol. xxx., supplement, part 1.—On the form of the crystalline cones in arthropod eyes, especially phronima, by Oscar Schmidt.—On anomia, with remarks on the muscular system of lamellibranchs, by H. von Jhering.—The poison apparatus of ants, by A. Forel, 41 pp. two plates.—The post-embryonic formation of limbs in insects, by H. Dewitz, dealing especially with formica, 28 pp.—Contribution to the structure and development of the lungs in mammals, by Ludwig Stieda; figures from embryonic sheep, mouse, and horse.—On the ornamental colouring of Daphnidæ, by August Weismann. The author believes the colour patterns are secondary sexual characters developed by sexual selection.—On the action of the voluntary muscles in land snails, by H. Simroth.

Vol. xxxi., part 3.—Researches on the structure and development of sponges, part 4, by F. E. Schulze; 42 pp., four plates. This part deals especially with the family Aplysiadæ.—Contribution to the development of feathers, by Dr. Th. Studer, Professor at Berne; the feathers of the Penguin, Megapodius, and Dromæus, are dealt with and figured in two plates.—On the fertilisation of the egg in *Petromyzon planeri*, by Ernst Calberla, with a discussion on fertilisation generally; 50 pp., two plates.—On the formation of ova, and on the male of *Bonellia viridis*, by Franz Vejdovsky.

Journal of the Russian Chemical and Physical Societies of St. Petersburg (vol. x. No. 4) contains the following papers:—On the action of peroxide of hydrogen upon the oxygen compounds of thallium, by E. Schöne.—On the action of iodine upon certain urea and amidogen compounds, by W. Roudneff.—On nitrophthalic and oxyphthalic acids, by O. Miller.—On the admixture of zinc in different parts of the body after the intoxication with acetate of zinc, by M. Mazkewicz.—On the action of water and oxide of lead on the halogen compounds of ethylene hydrocarbons, by A. Eltekoff.—On the action of the same substances upon bromide of diamylene, by the same.—On the action of trichlorolactic acid upon urea, by D. Cech.—On the magnetic induction of the two spheres, by O. Chwolson.

SOCIETIES AND ACADEMIES

LONDON

Geological Society, June 19.—John Evans, D.C.L., F.R.S., vice-president, in the chair.—Charles Louis Buxton, Wybrandts G. Olpherts, and William Phelps Richards were elected Fellows of the Society.—The following communications were read:—On the section of Messrs. Meux and Co.'s artesian well in the Tottenham Court Road, with notices of the well at Crossness, and another at Shoreham, Kent; and on the probable range of the lower greensand and palæozoic rocks under

London, by Prof. Prestwich, F.R.S., V.P.G.S. The well-known boring at Kentish Town in 1856 showed the absence at that point of lower greensand, the gault being immediately succeeded by hard red and variegated sandstones and clays, the age of which was at first doubtful, but which were finally considered by the author to approach most nearly to the old red sandstone near Frome, and to the Devonian sandstones and marls near Mons, in Belgium. The existence of some doubt as to this identification rendered the boring lately made at Messrs. Meux's brewery particularly interesting, and the method of working adopted by the Diamond-boring Company, by bringing up sharply cut cores from known depths, gave special certainty to the results obtained. The boring passed through 652½ feet of chalk, 28 feet of upper greensand, and 160 feet of gault, at the base of which was a seam 3 or 4 feet thick, of phosphatic nodules and quartzite pebbles. Beneath this was a sandy calcareous stratum of a light ash-colour, passing into a pale or white limestone, and this into a rock of oolitic aspect. Casts and impressions of shells found in this bed showed it to be the lower greensand, whose place it occupied. The boring was carried further in the hope of reaching the loose water-bearing sands of this formation, but the rock became very argillaceous, and, when 62 feet of it had been passed through, the boring entered into mottled red, purple, and greenish shales, dipping at 35° in an unascertained direction. These beds continued through a depth of 80 feet, when, their nature being clearly ascertained, the boring was stopped. The fossils of these coloured beds, which included *Spirifera disjuncta*, *Rhynchonella cuboides*, and species of *Edmondia*, *Chonetes*, and *Orthis*, show them to be of Devonian age. Thus, the existence of palæozoic rocks at an accessible depth under London and the absence of the Jurassic series, as maintained long since by Mr. Godwin-Austen, is experimentally demonstrated. These facts are of interest in connection with the question of the possible extension of the coal-measures under the cretaceous and tertiary strata of the south-east of England. The beds found at the bottom of Messrs. Meux's boring are of the same character as the Devonian strata which everywhere accompany the coal-measures in Belgium and the north of France, being brought into juxtaposition with them by great faults and flexures. The author refers especially to a remarkable section at Auchy-au-Bois, in the western extremity of the Valenciennes coal-field, which is particularly interesting from its furnishing evidence that the Hardinghen coal-field, between Calais and Boulogne, is a prolongation of that of Valenciennes, and because the same strike and a prolongation of the same great fault observed at Auchy-au-Bois through Hardinghen would carry the southern boundary of any coal-field in the south-east of England just south of Maidstone, thence passing a little north of London. Hence it is in the district north of London that there is most probability of the discovery of the carboniferous strata. The extent of country in which shafts could be sunk to the palæozoic strata will, however, be limited by the presence of the water-bearing lower greensand, which probably reaches close to London in the south, reappears in Buckinghamshire and Bedfordshire, thirty or forty miles north of London, and probably extends some distance towards the city under the chalk hills of those counties and Hertfordshire. The nature of the representative of the lower greensand in the boring, and the characters of the fossils contained in it, lead the author to the conclusion that in it we have a deposit produced near the shore of the neocomian sea, here probably consisting of cliffs of Devonian (or carboniferous) rock. From these cliffs the calcareous material which here replaces the usual loose sands of the lower greensand was perhaps derived by the agency of springs; and the shore-line itself must be situated between the south end of Tottenham Court Road and the Kentish Town boring. The sandy beds of the lower greensand will probably be found to set in at no great distance to the southward, presenting the conditions necessary for storing and transmitting underground waters. A test boring made by Mr. H. Bingham Mildmay at Shoreham Place, about five miles from Sevenoaks, and in which the lower greensand was met with at about the estimated depth (450 feet) and furnished a supply of water, seems to confirm these views.—Notes on the palæontology and some of the physical conditions of the Meux's-well deposits, by Charles Moore, F.G.S. The chief interest of Mr. Moore's investigations centres in the sixty-seven feet of strata intervening between the gault and Devonian. In this marly and oolitic-looking deposit he found no less than eighty-five different kinds of organisms, exhibiting a singular admixture of marine and lacustrine forms of life. Foraminifera are rare, but entomostraca and polyzoa are very abundant. Some genera are found, such as *Carpenteria*, *Saccammina*, *Thecidium*, and *Zellania*, of which the range in time is greatly extended by these investigations. The author fully confirms Mr. Etheridge's reference of the beds in question to the neocomian period, widely as they differ in physical characters from the lower greensand strata of the south-east of England. From a careful study of the nature and condition of preservation of the minute organisms, he concludes that the deposits which contain them were formed at first in shallow lacustrine hollows on the surface of the Devonian rocks now lying buried at a depth of 1,000 feet below London, and that these lakes were invaded by the waters of the neocomian sea, with the deposits of which their sediments were in part mingled, and under which they were finally buried.—The chair was then taken by Prof. Prestwich, M.A., F.R.S., vice-president.—On *Pelanechinus*, a new genus of sea-urchin from the coral rag, by W. Keeping, F.G.S., Professor of Geology in the University College of Wales.—Remarks on *Saurocephalus*, and on the species which have been referred to that genus, by E. Tulley Newton, F.G.S., of H.M. Geological Survey.—A microscopical study of some Huronian clay-slates, by Dr. Arthur Wichmann.—On a section through Glazebrook Moss, Lancashire, by T. Mellard Reade, F.G.S.—On the tertiary deposits on the Solimoes and Javary Rivers in Brazil, by C. B. Brown. With an appendix by R. Etheridge, F.R.S., and communicated by him.—On the physical history of the English lake-district, with notes on the possible subdivision of the Skiddaw slates, by J. Clifton Ward, Assoc. R.S.M., F.G.S.—On some well-defined life-zones in the lower part of the Silurian (Sedgw.) of the Lake-district, by J. E. Marr. Communicated by Prof. T. M'K. Hughes, F.G.S.—On the upper part of the Bala beds and base of Silurian in North Wales, by F. Ruddy. Communicated by Prof. T. M'K. Hughes, F.G.S.

Anthropological Institute, June 11.—Mr. John Evans, D.C.L., F.R.S., president, in the chair.—Dr. J. Beddoe, F.R.S., read a paper on the Bulgarians, referring more especially to the skull-form, on which he quoted Virchow and Kopernicki, but gave also some observations of his own. Not one of sixteen skulls hitherto examined, and procured in different districts of Bulgaria, presented anything like the true Slavonic type, though a few slightly approximated towards it. Almost all were of a cylindrical form, with a considerable parieto-occipital development, and a low, narrow, sloping frontal region; there was an absence of frontal parietal bosses; the skulls inclined to be long, except those few which indicated an admixture of the Slavic type. The majority nowise reminded one of either the Slavic or Turkic form, nor were they much like Esthonian skulls, but they were probably rather Ugrian than anything else. In some of them the great degree of prognathism, the deep nasal notch and horizontal nasal bones reminded Virchow of the Australian type. If the *physique* of the Bulgarians was a difficult and obscure subject, their *morale* presented its own difficulties. They differed from the Serbs in some points favourably; in more, perhaps, unfavourably, though some of their worst faults were doubtless what naturally arose in a subject race. The heroic type which appeared among the Serbs, whether they were Mussulman, Rayah, or free Christian, and culminated in the splendid barbarians of the Montenegro, was absent here. There was no chivalry, but mere ferocity, in their ballads. Their religion was little above Fetishism, and had little connection with morality. Manliness, generosity, truthfulness, and respect for women were scarcely to be expected of such a people; but ambition was there, and industry and acquisitiveness to a degree not found among the Serbs; and the desire of knowledge was there, and the capacity to learn, and, but for the interference of Russia, and the vast amount of moral and physical evil brought about thereby, they might gradually, under a government which, though faulty, was improving, have developed into better things.—Miss A. W. Buckland read a paper on the stimulants of the ancients and of modern savages. The paper commenced by stating that all races have acquired the use of stimulants in some form, but that the stimulants of the lower races, such as the Australian, consists merely of leaves and roots, chewed for their strengthening and invigorating properties, this being only a slight advance upon the instinct which prompts the inferior animals to seek out certain plants for medicinal purposes. The first step towards the manufacture of stimulating drinks is seen in the kava of the South Seas. This art of producing fermentation by the masti-

cating process can be traced in a line across the Pacific from Formosa, where rice is the ingredient thus employed, to Peru and Bolivia, where maize is used for the same purpose, the manufacturers being always women. The next advance is that acquired by agricultural races, who make a kind of beer from the chief cereal grown by them. This liquor probably reached our shores from Egypt, where it was very early known, through the lake dwellers, and still forms the principal drink of all African races. Pastoral tribes, meanwhile, use the milk of their flocks and herds and the honey of wild bees in the manufacture of their fermented drinks: hence the celebrated *koumiss* and *mead* of Scythic nations, the same liquors reappearing among the Kaffirs in South Africa, the vessels used in both countries being the skins of animals, which were also used for storing wines in the East. Later, in Greece and Rome mead was a favourite beverage of the Scandinavians and Anglo-Saxons, and there seems to be a shadow of the Scythic *koumiss* in the Devonshire liquor known as white or grout ale, whilst both liquors may be traced more distinctly in the famous *amrita* and *soma-wine* of the Vedas. Various plants and fruits have been used in all civilised and semi-civilised countries from very ancient times in the manufacture of wines, but grape juices had formerly a circumscribed range, having been confined to Western Asia, Egypt, Greece, and Rome, but forbidden in China and the vines extirpated. The religious ceremonies and prohibitions attached to these various beverages were briefly noticed, as also the deification of plants on account of their medicinal properties and the form and material of drinking vessels, whilst alcohol, the latest and most pernicious development of the art of manufacturing stimulants was only mentioned as not having been included among the beverages of the ancients nor known to savages until introduced by Europeans.—The Director then read a paper by Mr. John Sanderson on polygamous marriage in South Africa.

PARIS

Academy of Sciences, July 16.—M. Fizeau in the chair.—The following among other papers were read:—Remarks on the influence of atmospheric electricity of weak tension on vegetation, by M. Berthelot. *A propos* of M. Grandeau's experiments, M. Berthelot recalls his own, proving fixation of free nitrogen on organic matters under weak electrical action, &c., such action (in nature), being probably more efficacious than that of thunderstorms, owing to its duration and extent.—On a *brochure* of M. Hirn relating to whirlwinds, by M. Faye. M. Hirn distinguishes two kinds of descending whirling movements, represented by cyclones and by trombes. The former (he considers) are propagated naturally downwards by simple lateral communication of a gyratory motion, originating in the upper regions. They enlarge and diminish in rapidity (owing to friction). For the other class, which become more and more restrained in their transverse dimensions (and take the figure of an upright, not an inverted, funnel), he calls in a small force in the form of electricity of the clouds, and the attraction between them and the ground through an imperfectly conducting medium. M. Faye doubts this view, and supposes mechanical identity of the two phenomena.—Processes and apparatus for study of the velocity of propagation of excitations in different kinds of motor nerves in mammalia, by M. Chauveau. In this note he merely describes his mode of experimentation, which was on mammalia of large size, chloralised, or subjected to section of the bulb and artificial respiration. He used induced currents for the (uncovered) nerve, by the unipolar method. At each turn of an automatic distributer the current is passed to a different point of the nerve. The results of experiment are stated to differ from those of Helmholtz in his experiments on the nerves of a killed frog.—General Morin referred to the loss sustained by the Section of Mechanics in the death of General Didion, author of a "Traité de Balistique," &c.—On galvanoplasty of cobalt, by M. Gaiffe. Cobalt may be advantageously substituted for iron and nickel, as a protective layer for engraved and typographic plates. M. Gaiffe uses a bath of neutral solution of the double sulphate of cobalt and ammonia; the anode a sheet of platinum or (better) a plate of cast or forged cobalt. The current is kept at about six B.A. units, and reduced to three, when the whole piece has become white. The deposition may be made nearly as rapid as that of nickel.—On the existence of lesions of the anterior roots in acute ascending paralysis, by M. Vulpian. These lesions, found in every preparation (the spinal cord being unaltered), consisted in fragmentation of the myeline into drops and droplets, hypergenesis of the protoplasm of each inter-annular segment, and multiplication of the nuclei of Schwann's sheath. The cylinder-axis had completely disappeared.—M. Ducretet presented (through M. Du Moncel) a stethoscopic microphone of great sensibility. He utilises M. Marey's delicate tambours, the vibrations of sound from the body acting on the elastic membranes.—Discovery of a comet by Mr. Lewis Swift, at Rochester, U.S. (telegram from the Smithsonian Institution).—Measurement of the calorific intensity of solar radiations, by M. Crova. This relates to observations last year. The intensity at mid-day increased from the end of January to March 15, when there was a maximum of 1·320 cal. The minimum was on June 28 (1·023 cal.); then the radiation increased, and on October 16 reached the pretty high value of 1·260 cal. As before, the weakest radiations were with S. or S.W. winds and comparatively high temperatures; the strongest with N. or N.W. winds and low temperatures; the former winds increasing, the latter diminishing the vapour in the atmosphere. The author adds some observations on this last point.—On the reform of some processes of analysis in laboratories of agricultural stations, and observatories of chemical meteorology; volumetric determination of sulphate contained in water, by M. Houzeau. A new method for the latter is described.—The septicity of putrefied blood is destroyed by a very long contact with compressed oxygen at high tension, by M. Feltz.—Identity of nature of spontaneous and traumatic erysipelas; consequences, by M. Real. A discussion took place on explosions in flour-mills, *à propos* of a recent letter of Mr. Lawrence Smith from the United States.—Structure of the stem of Sigillaria, by M. Renault.

GÖTTINGEN

Royal Society of Sciences, March 2.—The following, among other papers, were read:—Comparative anatomy of the crystalline lens, by Prof. Henle.—The bursæ of Ophiura and their homologies with the Pentremites, by Prof. Ludwig.

May 4.—The systematic position of Sclerophylax and Cortesia, by Prof. Grisebach.—Observations on the pharmacology of Salicin, by Dr. Marmé.—Relation of the left intercostal vein to the vena azygos, by Prof. Brunn.—Some Avestic words and forms, by Prof. Bezzenberger.—Coptic-Arabian inscriptions in the University library, by Prof. Wüstenfeld.

CONTENTS

THURSDAY, AUGUST 1, 1878

THE ECLIPSE OF THE SUN

THE following telegram was received from Mr. Lockyer at the moment of going to press. It contains the fullest account of the results of the Eclipse, and of the conclusions arrived at by some of the most eminent of the observers engaged on it, which has yet been published:—

Corona smaller and less brilliant than in 1869 and 1871. Hydrogen faint in corona. Generally invisible, as was also the case in 1874. Ranyard's polarisation confirmed Young's law, both (?) and lines brilliant. Corona probably photographed in Siam (?). Fluorescent eyepiece worked well. Bright line near B; heat line in ultra red by thermopile. Watson's Vulcan, Right ascension 8° 26′, declination 18° N. Result—lower temperature of corona gas, as confined to chromosphere; almost entirely continuous spectrum, isolated from gaseous spectrum. Corona changes with sun-spots, and prominences increased. Continuation of absorption with deficit in ejected hot matter induces solar radiation. Young, Watson, Draper, Lockyer cable above.

The following telegram appears in the *Daily News* of yesterday from its special correspondent at Rawlings, Wyoming, U.S., under date July 29:—

The eclipse has been most satisfactorily observed at all the northern stations, and at all the southern ones from which news has been received up to the present time.

The corona was markedly different from those observed in 1869, 1870, and 1871, and this year the observations have demonstrated the great variation in the structure and condition of the sun's outer atmosphere when there are most and fewest spots on his disc. The corona was small, of a pearly lustre, and the indications of definite structure were limited to two portions. Several long rays were seen, and Prof. Newcomb, who had erected a screen on a high pole, thinks he detected the zodiacal light extending six degrees from the sun. Prof. Draper, who used a Rutherfurd grating two inches square and a camera of large aperture, and Mr. Lockyer, who placed a small grating in front of an ordinary portrait camera, both obtained photographs of the spectrum of the corona. A continuous spectrum only was recorded, and in ordinary spectroscopes the bright lines usually seen were altogether absent. Mr. Lockyer, who observed with a simple grating, saw no rings.

All these are so many indications of a wonderful change since 1871, and there is great probability that the substance which gives rise to the continuous spectrum is not that which produces any of the lines.

Prof. Newcomb's party and Prof. Barker made a careful search for the dark lines in the corona, but none were observed. Prof. Young has telegraphed that there were no lines observed in the ultra violet at Denver. It would appear, therefore, that he also has obtained photographic evidence of a continuous spectrum. The radial polarisation observed in 1871 has been confirmed by Prof. Holden.

A new use of the eclipse has been introduced on this occasion. Professors Newcomb, Watson, Holden, and others have included a search for intramercurial planets in their programme, and Prof. Watson has been fortunate enough to detect a body of four and a half magnitude near the sun, which certainly is neither a known star nor a planet.

Every facility has been afforded to the astronomers, and a fourth station along the northern line crossing the belt of totality was at the last moment organised by the Union Pacific travelling photographic car being run to a point between the Eclipse camps at Separation and Preston.

The tasimeter, the new instrument on which Mr. Edison has been working unceasingly here, has proved its delicacy. During the eclipse he attached Thomson's galvanometer, the index being set to zero, when the telescope carrying the tasimeter was pointed several degrees from the sun. The point of light rapidly left the scale, when the corona was brought upon the fine slit by which the tasimeter itself was protected. There was no chromosphere to speak of, and only one prominence, like the horn observed in 1868, but very dim.

OUR NATURAL HISTORY COLLECTIONS

ON referring to the "Bill to enable the Trustees of the British Museum to remove Portions of their Collection," our readers will see that our correspondent, "Naturalist," in our last issue (p. 328), is correct in supposing that this measure contemplates no change whatever in the administration of the natural history collections when placed on their new site in South Kensington. The fourth clause of the Bill expressly reserves all the "rights, powers, duties, and obligations" of the fifty trustees, except as regards the mere removal of the portions of the collections specified in the schedule. And we must agree with our correspondent that this measure will be directly contrary to the opinion of many of our leading naturalists, and to the recommendations of the Royal Science Commission.

As regards the first point, it is only necessary to refer to the memorial presented to the Chancellor of the Exchequer in 1866, when the subject of the removal of the natural history collection was under discussion. The memorial, which was drawn up primarily in *support* of the removal of the natural history collections from the rest of the British Museum, and is signed by Mr. Bentham, Mr. Darwin, Sir J. Hooker, Prof. Huxley, and other well-known names, states that in the opinion of the memorialists "it is of *fundamental importance* to the progress of the natural sciences in this country that the administration of the natural history collections should be placed under one officer, who should be immediately responsible to one of the Queen's ministers." The Bill as drawn proposes to leave the natural history collections exactly as they are, under the rule of fifty trustees responsible to no one but to themselves.

Let us now turn to the Fourth Report of the "Royal Commission on Scientific Instruction and the Advancement of Science," issued in 1874, in which the affairs of the British Museum, and more especially of the natural history collections belonging to it, are discussed. After an exhaustive account of the circumstances of the case and an analysis of the evidence given before them by the

leading naturalists of the day on the subject, the Royal Commissioners came to the following conclusions :—

1. That the occasion of the removal of these collections to the new buildings now being erected at South Kensington for their reception be taken advantage of to effect a change in the *governing authority and official administration* of that division of the museum.

2. That the director of the natural history collections should be appointed by the Crown, and should have the entire administration of the establishment under the control of a Minister of State, to whom he should be immediately responsible.

Now it is hardly necessary to point out that if the Bill before the House of Commons be passed in its present state (whereby all "the rights, powers, duties, and obligations" of the Trustees of the British Museum are expressly reserved), the recommendations of the Royal Commissioners will be treated as so much waste paper. If the Government appoints a Commission of the best men of the country to advise them on a subject of which they know nothing, it seems to us to be hardly civil to allow an Act of Parliament to be passed in the teeth of their deliberate recommendations without even taking the trouble to explain why these recommendations are not to be carried into effect. Yet this is what is now proposed to be done.

HULL'S GEOLOGY OF IRELAND

The Physical Geology and Geography of Ireland. By Edward Hull, M.A., F.R.S. (London: Stanford, 1878.)

THE great map of the veteran Sir Richard Griffith, followed by the detailed labours of other geologists, especially of the Geological Survey, and of its lamented director, the late J. B. Jukes, has explained the general geological structure of Ireland, and sketched, partly in outline, partly in considerable detail, the curious problems which that structure suggests. As yet, however, the abundant published information to be gleaned from papers and memoirs regarding Irish geology lies chiefly scattered through the *Transactions* of various scientific societies, and the Explanations of the Survey. Some of these publications are not nearly so widely known as they deserve to be, or as they assuredly would be if it were more easy for geological students in general to procure a reading of them. Mr. Hull has, therefore, done good service in preparing this little handbook to the geology and geography of Ireland. It is a most useful compendium of information, and its utility is greatly enhanced by the references to those works and papers where the subjects he discusses are more fully treated.

The volume is divided into three parts. In the first of these the author gives a digest of what is known regarding the geological formations of Ireland. In treating of the palæozoic rocks, he follows Harkness and others in regarding the metamorphic rocks of the north-western counties as the general equivalents of the unaltered Lower Silurian masses of the rest of the island, thus identifying both groups of rocks with those which occupy a similar position in Scotland. In this he is undoubtedly correct, and is quite justified by the sections published by Murchison and others. In these days, however, when almost every dictum of our fathers is called in question, and when able observers on both sides of the Atlantic are loudly proclaiming that they can find no true palæozoic gneiss and schist anywhere; when Alpine rocks—once devoutly regarded as metamorphosed Cretaceous strata—have been pushed back and back till their enemies will not let them have a footing among any even of the palæozoic formations, it certainly would be a good and serviceable piece of work to fix, if possible, by means of fossils, the horizon of the quartzites and limestones of Donegal, and to demonstrate, by numerous transverse sections, that these rocks pass truly, and with no deceptive overturn, beneath the younger gneissose and schistose masses. In Prof. Hull's necessarily brief summary he does scant justice to the Old Red Sandstone. To some extent he makes up for this by the greater fulness of his account of the Carboniferous system, to which he gives considerable interest by the parallelism, suggested by his long experience in Lancashire and elsewhere, between the established divisions of the system in England and the grouping which he has been able to recognise in Ireland. The fragments of Permian and Mesozoic deposits in the north of Ireland are duly mentioned; a more detailed description is given of the huge volcanic plateau of Antrim, and the successive stages of its history; while the Glacial and Post glacial formations receive tolerably ample illustration.

Having laid his foundation of facts, Mr. Hull proceeds, in Part II., to build upon it his explanation of the present physical geography of Ireland. Beginning with the mountains he arranges them in groups, and points out in each case the evidence of their age. The remark just made regarding the metamorphic rocks of Donegal may be repeated here in reference to the alleged age of these north-western mountains. Of course as Upper Silurian rocks lie against them and contain conglomerates derived from them, these heights must be far older than Upper Silurian times. The author assigns them to a long unrepresented interval between the Upper and Lower Silurian periods—a date to which the corresponding Scottish Highlands have also been referred. In dealing with the Wicklow Highlands so admirably worked out by Jukes and his colleagues, Mr. Hull suggests that as the granite there was certainly protruded before the Old Red Sandstone had been laid down, it may even have been earlier than Upper Silurian time, and "therefore synchronous with the mountains of Donegal, Mayo, and Galway." But the Old Red Sandstone of the South of Ireland, thick though it be, seems to represent only the upper member of that system. The vast period of the Lower Old Red Sandstone, so rife elsewhere in subterranean movements and volcanic outbursts, is not known in the south of the island, unless we may conjecture the Wicklow granite to belong to that epoch. The numerous and characteristic ridges and isolated eminences which in the south-western counties and in the central plain rise out of the Carboniferous plain, often with a central core of contorted Silurian rocks, are assigned to an interval of terrestrial disturbance between the Carboniferous and Permian periods. The evidence for this conclusion is fragmentary and has been skilfully marshalled into form by the author; but it cannot be regarded as by any means conclusive. Yet more uncertain is the reference of the Mourne Mountains to the Permian period. That

these heights are remnants of an ancient volcanic centre of later date than the Carboniferous Limestone has been made satisfactorily evident by the careful maps and sections of the Geological Survey. The rocks differ a good deal from those of the Tertiary volcanic region of Antrim. Mr. Hull thinks that they have not the same "appearance of recentness" as the latter, and as Permian volcanic rocks have been recognised in the south-west of Scotland, he thinks it a pity that the Emerald Isle should not have a share of them, and so he would fain regard the peaks of Mourne and Carlingford as the stumps of volcanoes which were blazing in the west when those of the Rothliegende were active in central Germany. All that, in the present state of our knowledge, can be affirmed about these rocks, is that they are later than the Carboniferous Limestone. They may be called Tertiary with about as much probability as Permian.

The wrongs of Ireland go back at least as far as the close of the Carboniferous period. Mr. Hull, with praiseworthy calmness, sketches the process by which his country has been despoiled of its once extensive coal-fields, and, while pointing regretfully to the few little scraps left here and there to tell of former mineral wealth, doomed to irretrievable destruction before either Celt or Saxon set foot upon the land, he consoles us with the just reflection that "the character of the inhabitants and their destiny as an agricultural or pastoral people were fixed altogether independently of social or political considerations." The author, following Jukes in his explanation of the history of Irish rivers, gives some interesting details regarding a few of the principal water-courses of the country. His account of the numerous lakes of Ireland is well arranged, but provokingly brief.

In the third part Prof. Hull deals with the glaciation of Ireland, and presents us with a readable summary of what is known up to this time on that subject, his narrative being accompanied by a small coloured map, on which the chief lines of ice-movement are drawn. Though certain tracts are marked on this map as "snow-fields," it is to be presumed that at the time the rocks were being striated in the directions there indicated, the whole island was one vast snow-field, with no boundary of any kind between the tracts here separated and the rest of the country. In a closing chapter the author brings before his readers the days of the mammoth, red-deer, rein-deer, great Irish deer, wolf, bear, and wild boar. To that venerable Irishman, the *Megaceros hibernicus*, a couple of pages are lovingly devoted, where we learn that the reason why he flourished so abundantly in the sister island was "the absence of many of the natural enemies with which he had to contend in Britain and Europe." Happy days these must have been! Who knows but Megaceros may have lived in brotherhood with the earliest human Irishmen until in after ages the "natural enemies" of both crossed over to them from Britain.

The volume is certain to prove useful. To geologists at a distance it presents in brief and readable form a compendium of all that is most striking and interesting in Irish geology. To those who can avail themselves of the numerous opportunities now afforded of visiting and travelling in Ireland it forms an admirable guide-book. Its appearance before the approaching meeting of the British Association is opportune. No member of the Association who means to see a little of Ireland after the Dublin congress is over should neglect to stow a copy of the book into a corner of his portmanteau.

ARCH. GEIKIE

OUR BOOK SHELF

A Treatise on the Cycloid and all Forms of Cycloidal Curves, and on the Use of such Curves in dealing with the Motions of Planets, Comets, &c., and of Matter projected from the Sun. By Richard A. Proctor. With 161 Illustrations and many Examples. (London: Longmans, 1878.)

THIS is a very full book on the curves enumerated; marked by much elegance in the geometrical portion of the work. It is by far the completest treatise we know, and is likely to take its place as a standard work on the subject. It is marvellous how much can be said about these curves, and one is ready to indorse Chasles' opinion—referring to the cycloid—"Cette courbe merveilleuse." Mr. Proctor only slightly glances at the historical side, and merely refers to Pascal's famous questions, a proof of which, we believe, could hardly, if at all, be effected by purely geometrical methods. Use has been made of De Morgan's article on trochoidal curves, the fullest previous exposition of the properties of these curves in relation to epicyclics, and the work, which is admirably printed, has had the advantage of being embellished with drawings from Mr. Perigal's well-known mechanically-traced curves (bicircloids). One section is devoted to the analytical equations to the curves, and the last section is a reprint of two papers which have already appeared in the *Monthly Notices* of the Astronomical Society, entitled "The Graphical Use of Cycloidal Curves to determine (1) the Motion of Planets and Comets, (2) the Motion of Matter projected from the Sun."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Microphone

THE pleasure with which those beautiful discoveries and inventions, the telephone, the phonograph, and the microphone, have been appreciated by the world, has been unhappily, and I must say I think unnecessarily, marred by one of the most disagreeable things that can be thrust on the public—a personal claim of priority, accompanied by accusations of bad faith, especially when made against any one of whose name and fame the public has come to feel concerned.

Before troubling the public at all with such a matter, Mr. Edison might surely have reasoned out his claim with Mr. Preece, with whom he had been from the beginning in correspondence, or he might have written immediately to public journals, calmly pointing out the close relation between his own "carbon telephone" and Mr. Hughes' subsequent "microphone." The scientific public could then have calmly judged, and would have felt much interest in judging, how much in common or how much not in common there may be in the physical principles concerned in the two instruments. But by his violent attack in public journals on Mr. Preece and Mr. Hughes, charging them with "piracy" and "plagiarism," and "abuse of confidence," he has rendered it for the time impossible for either them or others to give any consideration whatever to his claims. Nothing can be more unfounded than the accusations! Mr. Preece himself gave, at the Plymouth meeting of the British Association last August, a

clear and thoroughly appreciative description of Edison's carbon telephone, and published it in the printed reports of his lecture which appeared in the public journals. The beautiful results shown since the beginning of the present year by Mr. Hughes with his microphone were described by himself in such a manner as to leave no doubt but that he had worked them out quite independently, and that he had not the slightest intention of appropriating any credit due to Mr. Edison. It does seem to me that the physical principle used by Edison in his carbon telephone and by Hughes in the microphone is one and the same, and that it is the same as that used by M. Clérac, of the French "Administration des Lignes Télégraphiques," in the "variable resistance carbon tubes," which he had given to Mr. Hughes and others for important practical applications as early as 1866, and that it depends entirely on the fact long ago pointed out by Du Moncel, that increase of pressure between two conductors in contact produces diminution of electric resistance between them.

I cannot but think that Mr. Edison will see that he has let himself be hurried into an injustice, and that he will therefore not rest until he retracts his accusations of bad faith publicly and amply as he made them. WILLIAM THOMSON

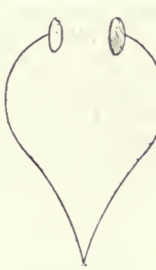
Yacht *Lalla Rookh*, Cowes, July 30

IT may be of interest at the present time to recall the fact that the word "microphone" was first employed by Sir Chas. Wheatstone upwards of fifty years ago. In a paper entitled "Experiments on Audition," published in the *Quarterly Journal of Science* for 1827, Wheatstone remarks:—"The great intensity with which sound is transmitted by solid rods at the same time that its diffusion is prevented affords a ready means of effecting this purpose [augmenting the loudness of external sounds], and of constructing an instrument which from its rendering audible the weakest sounds may with propriety be named a microphone." As the original paper may not be readily accessible, an extract from it is appended to this letter, wherein will be found a description of the simple arrangement proposed by Wheatstone—it is in fact a metallic binaural stethoscope—together with some experiments with the instrument given by the author. The entire paper will appear in the republication of Wheatstone's scientific papers, which the Physical Society will shortly issue, and the instrument itself can be obtained for a trifling sum from Mr. Yeates, of King Street, Covent Garden.

Monkstown, Dublin, July 29 W. F. BARRETT

"Procure two flat pieces of plated metal, each sufficiently large to cover the external ear, to the form also of which they may be adapted; on the outside of each plate, directly opposite the meatus, rivet a rod of iron or brass wire about 16 inches in length, and one-eighth of an inch in diameter, and fasten the two rods together at their unfixed extremities, so as to meet in a single point.

The rods must be so curved, that when the plates are applied to the ears, each rod may at one end be perpendicularly inserted into its corresponding plate, and at the other end may meet before the head in the plane of the medial line.



Wheatstone's microphone, 1827.

The spring of the rods will be sufficient to fix the plates to the ears; but for greater security ribands may be attached to each rod near its insertion in the plate, and be tied behind the head. A more simple instrument may be constructed to be applied to one ear only, by inserting a straight rod perpendicularly into a similar plate to those described above.

The microphone is calculated only for hearing sounds when it is in immediate contact with sonorous bodies; when they are diffused by their transmission through the air this instrument will not afford the slightest assistance. It is not my intention in this place to detail all the various experiments which may be made with this instrument; a few will suffice to enable the experimenter to vary them at his pleasure:—

1. If a bell be rung in a vessel of water and the point of the microphone be placed in the water at different distances from the bell, the difference of intensity will be very sensible.

2. If the point of the microphone be applied to the sides of a vessel containing a boiling liquid, or if it be placed in the liquid itself, the various sounds which are rendered may be heard very distinctly.

3. The instrument affords a means of ascertaining, with considerable accuracy, the points of a sonorous body at which the intensity of vibration is the greatest or least; thus, placing its point on different parts of the sounding-board of a violin or guitar whilst one of its strings is in vibration, the points of greatest and least vibration are easily distinguished.

4. If the stem of a sounding tuning-fork be brought in contact with any part of the microphone, and at the same time a musical sound be produced by the voice, the most uninitiated ear will be able to perceive the consonance or dissonance of the two sounds; the roughness of discords and the beatings of imperfect consonances are thereby rendered so extremely disagreeable, and form so evident a contrast to the agreeable harmony and smoothness of two perfectly consonant sounds, that it is impossible that they can be confounded."—*Quarterly Journal of Science*, 1827, Part II.

The Meteor Shower of Aquarids (July)

ON July 27 ninety-three shooting stars were seen here, between 10h. 30m. and 14h. 30m., which, after making allowance for time occupied in charting the paths, is equivalent to about twenty-nine per hour for one observer. There was a rich shower of *Aquarids* from a point near μ Aquarii, at R.A. 343°, 14° S. declination, which gave twenty-two meteors. These were rather bright, not very swift, with moderately long paths (averaging 17°), and quite devoid of streaks. I had seen about five meteors of this system on the preceding night, and on the 28th I watched a very hazy condition of sky—in which the stars shone dimly—for four hours, and of forty-four meteors seen five or six others were *Aquarids*. This active shower was well seen by Capt. Tupman on July 27, 1870, with an accurately-defined radiant at 340°—14°, from fourteen meteors (see No. 43 of his catalogue), and on the four following nights he traced about forty-seven others from the same shower, though the centre seemed a little further south, at 340°—19° on the 28th. On the 27th he recorded seven meteors of this stream within the twenty-one minutes, from 14h. 3m. to 14h. 24m. It was also seen by me, at 342°—12° (ten meteors), on August 3-17 last year; and Schmidt gives radiants at 337°—11° for July 20-31, and at 344°—11° for August. Neumayer, in the southern hemisphere, also has a position at 337°—10° (July), and Heis at 339°—10° for July 27-31. The average centre from these eight independent determinations is at 340°—13° for this important shower, which evidently comes to a strong maximum on about July 27-29. The end of July has long been known as a meteor-epoch of considerable intensity, with a maximum, according to Quetelet, between the 27th and 29th, which is thus amply confirmed by recent observations, and proves these *Aquarids* to be but little less in importance to the annually-recurring showers of *Lyrids*, *Orionids*, *Taurids*, and *Geminids*.

It should be pointed out that, in future observations of this special shower, care must be taken not to confuse it with other contemporary showers in Aquarius. There are two radiants on or near the equator in about R.A. 334° and 349°, and one (of very slow meteors) at about 336°—6°, also a fourth at 326°—12° (mean position of five radiants seen by Schmidt and Tupman). They are distinct showers, though separated with difficulty, owing to proximity of position; and it is interesting to note that, if we average them with the strong radiant at 340°—13° referred to above, we have a central radiant at 337°—6°, which coincides exactly with Mr. Greg's position for the *Aquarids* (Nos. 109 and 137 in his catalogue of 1876), which apparently continue from July 5 to October 31. W. F. DENNING

Ashleydown, Bristol, July 29

P.S.—My observations were continued on the night of July 30, when seventy-six shooting stars were seen in four hours; thirteen of these were *Aquarids*, and seven of them visible in the half an hour preceding midnight, after which few were observed. From this I infer that the maximum had probably occurred on the morning of the 30th, when, unfortunately, a thick haze prevented work.—W. F. D.

Physical Science for Artists

WILL you permit me, through your columns, to tell Mr. Abbay that the phenomena—"les rayons de crépuscule"—he

refers to in his letter in NATURE, vol. xviii. p. 329, are of not unfrequent occurrence on the west coast of India, in the plains as well as the highlands. Moreover I can recollect being much struck with the appearance whilst travelling in Ireland in the autumn of 1863. The convergence of rays in the east, while the sun was setting, was then new and singular to me, but I have since often observed the phenomenon.

On some occasions the atmosphere has seemed clear, until sunset, when the blue sky has literally reddened, and it is then that the cloud shadows show best as bands of blue stretching from west to east, and visible in the zenith as well as nearer their converging points. E. H. PRINGLE

Clevedon, July 27

Taunton College School

IN your last number, in an article by Mr. Shenstone, of Exeter School, on the formation of a laboratory, he incidentally speaks of the council of this school, of which I am headmaster, as having "quenched the torch of science in the west." As this statement may be prejudicial to me, and can only arise from Mr. Shenstone's being imperfectly acquainted with the facts, I trust to your spirit of fairness to allow me to state publicly (1) that the senior half of the school in the last six months has been through a course of electricity and magnetism illustrated by experiments, and has just passed a creditable examination in those subjects under a Cambridge examiner of high reputation; (2) that there has been a course of lectures on botany this term; (3) that all those boys whose interests require it have been taught chemistry; (4) that we have had a very favourable report of the boys' proficiency in mathematics, which I presume, has some claim to be considered science, though to my great surprise at the present day it is often spoken of as if it had none. The council have left me perfectly free to teach as much or as little science as I choose; I choose, and in all probability always shall choose, to give every opportunity of acquiring scientific knowledge to my pupils, consistent with their instruction in other necessary subjects, and if I find any with strong scientific tastes, to foster them to the utmost. As my academical position was mainly, though not entirely, due to my scientific knowledge, it would be strange if I acted otherwise.

HENRY PEARCE KNAPTON

Taunton College School, July 27

Deep-sea Dredgings off the Gulf of Mexico

I WISH to correct an omission of mine in a notice of the work of the United States schooner *Blake* (NATURE, vol. xviii. p. 198). Capt. Sigsbee's modification of Thomson's wire-sounding machine was used for the deep-sea soundings. The steel wire was No. 20 American gauge, and the time required to reel in with it was always one minute per 100 fathoms. The steel wire rope used for dredging, which was made expressly at the suggestion of Prof. A. Agassiz, was the one mentioned in the notice as being of galvanised steel, with a hemp core (not coil, as printed), and which in the notice appears as if it were the same wire rope that was employed for sounding. The sentence will read correctly if the words "used for dredging" be inserted after the words "the wire rope" in the paragraph. The importance of this suggestion of Prof. Agassiz will be best understood when the immense saving of space gained—one coil of 3,000 fathoms of this wire rope occupying on the reel only a space of 5 feet long, 5 feet high, and 4 wide—and the immense saving in time of lowering and hoisting the dredge, are taken into account.

E. P. W.

ANTHROPOLOGY IN FRANCE [1]

IN the numbers of the *Bulletins* of the French Anthropological Society for 1876 are many papers of importance, some of which we shall briefly bring before our readers.

An admirable series of photographs of natives of New Caledonia, taken by order of the local French authorities, has been made the subject of some interesting notices by M. Paul Topinard. Comparing these pictures and a number of the skulls of indigenous New Caledonians with those of native Australians, he finds that while the former exhibit a greater unity of type than the latter, they also differ from them in presenting a roundness in the contour of the face, due to a predominance of the cellular tissue, which contrasts strongly with the well-marked muscles of the Australian. Their affinity with the negro and New Guinea Papuan types is incontestable. M. P. Topinard discusses in another paper the relative merits of the craniometric and facial modes of measurement, adopted the one by Daubenton and Camper, the other by Blumenbach, and Prichard, and the results obtained by M. de Quatrefages with the instrument invented by him, and named *goniomètre pariétal.* The speaker considers Prichard in error when he attempts to include all Mongolian groups generally under his so-called "ogival" cranial form, this form belonging, in fact only to the Esquimaux.—M. Lagneau wishes to draw the attention of anthropologists to the peculiarities still observable in the people of some parts of La Gironde, known as "Gavaches," or "Marotins," who are descended from certain Angevins, called into the district in about 1525, to repair the ravages caused by a virulent epidemic. In their indolence and slowness they differ strikingly from the vivacious Gascons, among whom they live.—The discovery in the lacustrine houses of Switzerland and Savoy, and in the Lake of Bourget of bronze rods, surmounted with movable rings, has called forth explanations from all quarters. Carl Vogt, among others, has come forward in response to M. Mortillet's invitation to supply him with a clue to their use, and according to him we still have a similar instrument in the "Ringelstock" of the German herdsman, which is formed of a stout nut-stick, terminating in a lateral branch, on which are hung several metal rings. If the noise is not successful in bringing back the animal, the instrument is thrown at its head with an alarming clatter of bells. M. Hamy entertained the members of the society with an account of the eccentricities of Siamese and Chinese fashion in the development of the finger-nails, which, according to some of the fac-similes laid before the meeting, at times attain a length of forty, and even forty-five centimetres, although usually only that of ten or twelve centimetres; in most instances this process of lengthening carries with it a corresponding twisting and interlacing of the nails, which acquire the semblance of antlered horns.—M. Bertillon has for some time been engaged in a careful analysis of the preponderance of one sex over the other in first or second legitimate, and illegitimate births in France, and some other countries, more especially Austria. He finds that in France to every 100 females born alive, there are 105 males; while in regard to still-born births the excess is as 137 to 100. These relations are, however, found to differ essentially when illegitimate births are considered alone, in which case the proportion is as 1,031 males to 1,000 females. In Austria, where the official reports kept of the sex of first and second births admit of more precise calculations in regard to this point, it is found that first births are more frequently masculine, in the proportion of 110·3 to 100; second births being as 105·2 males to 100 females, while the general relation of the sexes for all births is as 106 males to 100 females. This, however, applies only to legitimate births; the proportion falling in the illegitimate to 105 males against 100 females. MM. Lagneau, Broca, and others, took part in the discussion which followed on the reading of M. Bertillon's paper on the Influences of Primogeniture on Sex. In relation to this subject we may refer to M. Sanson's report (laid before the society on May 4, 1876) of the influence of age, vigour, &c., on the offspring, as noted by himself, on sheep and other domesticated animals.—French local archæology and palæontology have received careful attention from the society during the past year. M. Pommerol has described the curious megalithic monuments which are to be found in close vicinity to the mineral springs, ancient mortuaries, and church at Saint-Nectaire, in Auvergne. A dolmen, hitherto known only to the local peasantry

[1] *Bulletins de la Société d'Anthropologie de Paris.* Tome onzième, 1876.

has been cleared from the superincumbent foliage and opened, revealing remains of skeletons which appear to belong to the polished stone-age. M. Lepic has discovered a series of bone-caves near Soyons on the Rhone, and known as La Caverne de Néron. Here human remains are found intermingled with rhinoceros, elephant, horse, and reindeer bones, an immense number of flints, hatchets, arrow-heads, &c. M. Lepic, in extending his explorations to the plain of Soyons, above these caverns, discovered unmistakable remains of human habitations, together with the ordinary kind of bone, silex, and other *débris*. In the latter, however, was found a large hatchet formed of hematite, the first of the kind met with; fragments only of the stone having been hitherto obtained. In the grotto of Savigny stag-horn tools have been found precisely similar to those in use among the Lapps and Esquimaux for smoothing down the rough seams of their skin garments. At the aqueduct at Nîmes a Celtic inscription in Greek characters has been brought to light, this being the third of the kind found in Southern Gaul. The Abbé Maillard has made a careful survey, and drawn up a comprehensive plan of the so-called prehistoric stations at Thorigné-en-Charnie. M. de Prunières has laid before the society the results of his examination of the dolmens of l'Aumède Lozère, in which he had found an enormous mass of human bones belonging, for the most part, to a dolichocephalic race. The great number of the cranial bones, which presented perforations and cicatrised margins, confirms the view that trepanning was resorted to by primitive men for various pathological conditions.—M. Fischer's paper on cave-conchology and his reference to the identification of Isle of Wight fossils at Langerie-Basse, led to an interesting discussion on the question whether navigation could date as far back as the age of bone caverns, or whether different geographical relations alone could explain the presence of shells far from their centres of origin.—M. Boyer has made the skulls found in the Puy-de-Dôme caves the subject of careful study, and shows that a greater variety of type is to be met with than is usually admitted, while M. A. Roujon has turned his attention to the general anthropology of the district, which has led him to the assumption that five distinct types have succeeded one another in France.—M. Mortillet has presented the society with a copy of a map of prehistoric France, drawn up by him for M. Elisée Réclus' "Géographie Universelle," in which he has noted down all stations, caves, and dolmens discovered up to the present time.—M. Piette has drawn up a report of the remains in France of a Gallic civilisation, as exemplified in the collections brought together in the exhibition held at Rheims in 1876. One of the most important of the papers included in the *Bulletins* under consideration is M. Lagneau's exhaustive review of the ethnic distinctions between Celts and Gauls, a question which necessitates a careful reference to classical authorities, and seems still far removed from any satisfactory determination.—Another question similarly open to discussion, although widely different in character, is considered by M. Topinard, who has made the publication of his manual of anthropology the occasion for discussing the differences of meaning, to be practically attached to the terms ethnology, anthropology, and ethnography. A summary of such a paper would be of little use, and from the minutely-detailed series of definitions which the writer has thought it necessary to give, it would appear that Frenchmen have been less ready than ourselves to accept the more special meaning of anthropology as applied to man zoologically, and distinct from man when considered in reference to characteristics of race.

OUR ASTRONOMICAL COLUMN

THE TOTAL SOLAR ECLIPSE OF MAY 28, 1900.—In a recent note upon solar eclipses that will be total upon the North American continent, reference was omitted to one in the last year of the present century. On May 28, 1900, the moon's shadow will traverse the southern part of the United States territory, entering it near New Orleans and passing off in Chesapeake Bay. The elements of this eclipse are as follow:—

G.M.T. of Conjunction in R.A., May 28, 1900, at 2h. 56m. 22s.

	°	′	″	
R.A.	64	56	48·5	
Moon's hourly motion in R.A.		37	16·9	
Sun's „ „		2	32·4	
Moon's declination	21	50	17·1	N.
Sun's „	21	27	15·3	N.
Moon's hourly motion in declination ...		2	38·5	N.
Sun's „ „ „ ...		0	24·2	N.
Moon's horizontal parallax		58	26·6	
Sun's „ „			8·8	
Moon's true semi-diameter		15	55·6	
Sun's „ „		15	47·0	

The central eclipse begins in 116° 34′ west of Greenwich, latitude 18° 0′ N.; it occurs at apparent noon in 44° 50′ W. and 44° 57′ N., and ends in 31° 45′ E. and 25° 21′ N. Other points upon the line of central eclipse in American longitudes are:—

	Long. ° ′	Lat. ° ′		Long. ° ′	Lat. ° ′
Long.	96 15 W.	Lat. 27 9 N.	Long.	76 4 W.	Lat. 36 45 N.
„	90 9	„ 30 7	„	70 29	„ 39 1
„	86 28	„ 31 57	„	58 23	„ 42 47
„	79 17	„ 35 20			

At New Orleans the eclipse will be total for about twenty-five seconds, commencing at 7h. 29m. 23s. A.M.; local mean time with the sun at an altitude of 30°, and at the point 76° 4′ W. and 36° 45′ N., totality will begin at 8h. 47m. 27s. A.M., and continue 1m. 39s., which is about the longest duration of the total eclipse in United States territory, and indeed the longest available for observation upon land, on this occasion. After traversing the Atlantic the moon's shadow enters Portugal near Ovar, where totality lasts 1m. 30s., and passes off Spain about ten miles south of Alicante. In Alicante the total phase will commence at 4h. 10m. 11s. P.M., local mean time, ending at 4h. 11m. 29s. At Greenwich a partial eclipse is visible, magnitude 0·68, at 3h. 54m. P.M.

COMETARY NOTES.—Tempel's comet was detected at the observatory of Arcetri, Florence, on July 19, and as stated last week by Prof. Winnecke at Strasburg on the following evening. From the Strasburg observation it appears that the comet will arrive at perihelion September 7·1646 G.M.T. It has also been observed in this country with the aid of the ephemeris, given in this column.

Of the supposed comet reported to have been discovered by Mr. Lewis Swift on July 7, we have no further intelligence.

In a communication to the Royal Astronomical Society, Mr. Tebbutt, of Windsor, New South Wales, puts upon record the circumstance of his having first determined the orbit of the great comet of 1861, in addition to having been its first discoverer (on the night of May 13). Mr. Tebbutt's name was not associated with this grand object in Europe, in the same manner that the great comet of 1858 had been associated with the name of Donati, for the simple reason that there being no telegraph from Australia in that year, the news of his discovery did not reach Europe till the comet had so far diminished in brightness as to be of interest only to the astronomer. Otherwise a message by cable that a large comet discovered by Mr. Tebbutt might be looked for above the European horizon at the end of June, would doubtless have led to "Tebbutt's comet" being as universally known as was "Donati's comet" three years earlier. The period of revolution of Tebbutt's comet is just under 400 years, while that of Donati's is little short of 2,000.

Encke's comet will just be coming into view at the

observatories of the southern hemisphere, where it is important for the theory of this body that observations should be continued as long as practicable. It was in perihelion on July 26. At the next return in 1881, its track in the heavens will be very favourable for observation in these latitudes.

THE SATELLITE OF NEPTUNE.—In the *Monthly Notices* of the Royal Astronomical Society for June, Mr. Marth has furnished data founded upon Prof. Newcomb's tables, from which the position of the satellite of Neptune may be readily determined for any time during the approaching opposition; but with the approximate times of superior and inferior conjunctions (the angles being 311° and 131° respectively) which are appended, the part of the orbit in which the satellite must be found is easily ascertained without calculation. As has been known since the year 1853, the orbital motion of the satellite is retrograde.

GEOGRAPHICAL NOTES

THE distinguished Italian traveller and naturalist, Sig. L. M. D'Albertis, who has been exploring different parts of New Guinea since 1872, and in 1876-77 made two expeditions into the interior of that country by the Fly River, has arrived in London with his large collections in every branch of natural history.

DR. VAN DER HORCK, who lately made so valuable a tour through Lapland to the Arctic Ocean, is at present organising in Berlin an expedition for the especial purpose of studying the question of the original settlement of America by Asiatics. It is intended that the expedition, which will last from three to four years, shall coast along the entire eastern shore of Asia, up to the Polar Sea, visiting all the chief islands by the way, and then, crossing at Behring's Straits, follow the American coast to San Francisco. The expedition will follow the customary programme of a scientific voyage, making surveys, dredging, collecting objects in natural history, &c. The anthropological features will, however, be the most important, and every effort will be put forth to collect and classify all existing clues to a distant emigration from Asia to America. It is hoped that evidences in this direction may be found on the isolated groups of islands in the more northerly regions. Ample funds have been put at the disposal of the expedition, and it starts under the auspices of the German government and the Berlin Geographical Society.

THE services of the scientific element in the recent Berlin Congress have been recognised by Her Majesty's conferring the honour of knighthood on Mr. Edward Hertslet, C.B., F.R.G.S., Librarian of the Foreign Office and Keeper of the Archives, who perhaps had as much to do with the settling of the boundaries of the new states as the Prime Minister himself.

THE United States Coast Survey steamer *Blake*, which returned some weeks ago from dredging operations in the Gulf of Mexico, is now refitting for another expedition in November. Capt. Patterson, of the Coast Survey, we learn from the *Tribune*, says that the extensive and accurate soundings of the Gulf taken by improved scientific methods in the recent expedition, do not tend to confirm the belief, long held, that the equatorial current, after rushing from the Caribbean Sea through the channel formed by the West India Islands and the northward projection of Yucatan, makes the whole tortuous circuit of the Gulf close by the shores of Central America, Mexico, and the southern coast of the United States, before emerging into the Atlantic between the point of Florida and the Bahamas. The observations tend rather to prove that the force of the incoming equatorial stream expends itself in one direction against the mass of the Gulf long before it reaches the Texas coast, and then turns directly toward and reissues into the ocean. The old theory in regard to the current being unsettled, the expedition now to be made will proceed to repeat certain experiments, and to make others, with the view of either confirming or destroying the latter hypothesis. Exhaustive observations will be made of the region of ocean in and around the eastward islands of the Caribbean Sea, through which the equatorial current makes its entrance, as through a sieve, from the Atlantic into the long channel, 1,500 miles long, formed by the West Indies on the one side and Central and South America on the other, and leading to the Gulf of Mexico. From the experiments and observations of this expedition Capt. Patterson hopes for results which will go far toward laying at rest all merely speculative theories relating to the Gulf Stream. In connection with the investigations hitherto conducted by the Coast Survey expeditions in the Gulf of Mexico, it has been ascertained that the vast current of water pouring from the Gulf into the Atlantic, through the Florida and Bahama gate, has neither the same velocity nor the same temperature. It is believed by Capt. Patterson and his associates that further attention to this curious fact may develop results having an important bearing upon the science of climate and meteorology, making predictions possible as to changes in the seasons of the European countries affected by the Gulf Stream from the observed quantity and temperature of the flow through the Florida Straits.

THE Paris Geographical Society has recently received some interesting intelligence respecting M. Savorgnan de Brazza's explorations on the upper part of the River Ogowé, in Western Equatorial Africa. Having learned from the natives at Dumé that there were some falls on the Ogowé, in the Aduma country, he got together with some difficulty a party to show him their locality. On the way up the river the inhabitants fled from their approach, as they believed that white men brought small-pox with them. On the fourth day the expedition encountered the first rapids on the Ogowé after leaving Dumé; they became more and more numerous, and the breadth of the river diminished considerably. Further on sand-banks extended across the river, which became a succession of rapids in the country of the Atzianas. Among the Akanigues, higher up, the villages are described as very numerous and close together, and the country well cultivated and mountainous; the inhabitants collected on the banks to see the expedition pass. On the tenth day the explorers arrived at the River Passa, which has a strong current, and which is nearly as important as the Ogowé, there become comparatively narrow. On the following day they found themselves face to face with a large sandbank and a strong rapid, which their guides declared to be impassable. Dr. Ballay, one of the party, went by land to Pubava, some twelve miles above the rapids, and found that the Ogowé is not more than twenty metres broad above the falls; he thinks that the River Passa will probably furnish a more convenient route to the eastward than the Ogowé.

AS might be expected, Petermann's *Mittheilungen* for August is largely devoted to papers bearing on the recent changes in the East. First we have an article, written before the conclusion of the Berlin Congress, on the territory claimed by Russia from Turkey in Asia. Next comes an important study on the Kara Kum desert, with reference to the proposed Central Asiatic railway. Following this is a series of tables of population statistics on the Sanjak of Seres, in Macedonia. There is also an important paper on Herero Land, in South Africa, to accompany a new map of the region, based on the observations of the Rhenish missionaries, especially those of Herren Böhm and Bernsmann. The number concludes, as usual, with Dr. Behm's admirable monthly summary. Besides the map of Herero Land, there are maps of Armenia, to show the region claimed by Russia, and of

the south-east of Europe and Turkey-in-Asia, as re-adjusted by the Berlin Congress.

THE Buenos Ayres *Standard* furnishes some particulars of interest concerning Don Francisco P. Moreno's explorations in Southern Patagonia. The River Gallegos, it appears, has a mean velocity of four to five miles an hour, and is fed by the snows which fall in winter on the volcanic lands. It has two sources, which unite after a short distance, and two small tributaries to the south. The valley could be utilised for agriculture; on both banks mounds of lava are met with towards the south, forming black rocks with broken fragments like columns, wearing an appearance of an ancient city in ruins. All these peaks as far as Cape Virgin are extinguished volcanoes, of an average height of 860 feet. Don F. Moreno believes these eruptions to have been entirely independent of the Andine volcanoes. Between Gallegos and the banks of the San Gregorio, where these peaks are found, they have risen more irregularly than in other parts of Patagonia. The road winds capriciously through low valleys, watered by pools and rivulets, then through sterile tracts, and now and again over grassy elevations. At the confines of the Meseta (table-land) the face of the country changes. To the right the blue and white line of the snow-clad mountains stands out in relief. To the left is seen the summit of San Gregorio, then the narrow Straits, and further off the Fuegian Plains, enveloped in fog and lurid fires. At the Brunswick Peninsula on the Straits the landscape is particularly verdant and undulating, with mineral veins here and there and small woods of the "Calafate" (*Berberis*), which produces a delicious fruit. With regard to the climate of these southern regions, in the western part rain and storms are continual, and it would be difficult to populate it, but on the east the climate is more favourable, and those sudden and terrible atmospheric changes that cause so many shipwrecks are unknown. Don F. Moreno is of opinion that the climate from the River Santa Cruz to Cape Horn may fairly be compared to that of Great Britain, from the English Channel to the north of Scotland. On the high lands it is dry, with night dews, but little rain. In winter snow falls, but in spring, summer, and autumn, the climate is delightful, with some few days of intense heat.

THE new part of *Appalachia*, the journal of the Appalachian Mountain Club, contains Prof. Scudder's presidential address, an exhaustive summary of the various North American surveys, and explorations during the previous years. There are other valuable papers connected with the exploration of the Appalachians; one by Prof. C. H. Hitchcock gives an account of a large number of glacial markings in the White Mountains.

A WORK of great interest is now in course of publication at Vienna (Hartleben): "Die Sahara—von Oase zu Oase," by Dr. Joseph Chavanne. Up to this date twelve parts have appeared; they give excellent descriptions of the great African desert itself and of the tribes frequenting it. The scientific materials are worked out into attractive pictures with considerable skill; the reader travels in thought through the Oasis of Ziban, then makes the acquaintance of Biskra and its people, the so-called Paris of the desert, passing across the El Arnat and through the land of the Beni Mzab as far as In Salah and Tafilet. Numerous well-drawn illustrations add considerably to the attractions of the work.

A NEW book of special interest at the present time has just been published by Cotta, of Stuttgart. Its title is "Cypern, Reiseberichte und Landschaft, Volk und Geschichte." The author is Herr Franz von Loeher.

LETTERS have been received in Holland from Vardö, reporting that every one on board the *Wilhem Barentz*, the schooner of the Dutch Arctic Expedition, was in excellent health, and that hitherto the vessel had behaved admirably.

ON PREHISTORIC REMAINS IN BRUNSWICK[1]

A LARGE quantity of prehistoric remains have been found in the diluvial loam of Thiede and Westeregeln, in the Duchy of Brunswick. This fossil fauna of Thiede numbers about thirty species—the common loess molluscs (*Helix hispida*, *Pupa muscorum*, *Succinea oblonga*), together with remains of horse, reindeer, *Rhinoceros tichorinus*, *Elephas primigenius*, some carnivora, and rodents (as lemming, *Myodes torquatus*, *Arvicola gregalis*, &c.). The lemmings appear especially in the lowermost beds, with some few remains of reindeer and Arctic fox; in the middle beds they are associated with remains of horse, rhinoceros, and elephant, and gradually disappear in the higher horizons.

The fossil fauna at Westeregeln, numbering more than thirty species of mammals alone, is far more abundant and more varied. The mammals are bat, shrew, hyena, lion, wolf, Arctic fox, bear, badger, and especially rodents, all of them (the hare excepted), such as habitually live in holes underground, in steppe-like regions. Among them is *Arctomys bobak*. The remains of *Spermophilus altaicus*, of *Dipus*, and of several species of *Arvicola*, are extremely abundant. Lemming, hare, and lagomys are also met with. The presence of horse, reindeer, bos, and antelope has been ascertained, together with some few bones of *Elephas primigenius* and *Rhinoceros merki*. A well-developed trapezium of a peculiar horse may be possibly interpreted as a connecting form between *Equus* and *Hipparion*. The dental system of *Spermophilus* offers likewise some remarkable particularities. The birds are represented by eleven species—ducks, *Gallinaceæ*, pigeon, lark, bustard, vulture, and largely by species of *Fringilla* and *Hirundo*. Remains of bactrachians (*Bufo*, *Rana*, and *Hyla*) abound in certain localities. Of fishes only one-half of a pike's lower jaw has been met with. The number of molluscous species amounts to seven. The co-existence of insects may be inferred from the presence of many insectivorous mammals and birds.

Man's co-existence is attested at Thiede by axes of the stone period, found immediately beneath the humus; also by flint implements, and traces of fire-places in the lower beds of the loess. At Westeregeln splinters of flint, small fragments of charcoal, and broken bones of animals, indicate the presence of human beings, either permanent or occasional, during hunting excursions. According to Mr. A. Nehring, the discoverer of these deposits, their fauna approximates to the Steppe fauna of south-west Siberia, and is co-eval with the post-glacial period, when Northern Europe had an extreme continental climate. In the neolithic period, this fauna, as indicated by the remains of deer, bear, and beaver, assumed a sylvan character, persisting down to the times of Cæsar and Tacitus.

Mr. Nehring supposes the loam in question to have been transported and deposited by water, admitting, however, the occasional transport of materials by storm winds. Dr. Tietze thinks that the presence of fishes and batrachians offers no objection to the sub-aerial, or wind-origin, of this loess, as fishes, frogs, lizards, and tortoises, live on the steppes of Persia, and are even characteristic of their fauna; and fishes are also found in the artesian wells of the Sahara. Some known facts support the idea of the sub-aërial origin of deposits in localities having nothing in common with steppes. In 1866, the wind blowing from the south, the snow was covered with a stratum of yellow dust; the same phenomenon was observed at Kasan in 1872. Mr. D. Stur ascribes to the action of winds the recent thin layers of quartzose and micaceous particles accumulated on the slopes of the limestone Alps.

THE TAY BRIDGE

THE new bridge across the Tay, at Dundee, recently completed according to the plans of Mr. Bouch, M.I.C.E., by Hopkins, Gilkes, and Co., of Middlesborough, is the longest structure of its kind in the world. What renders it more remarkable than its enormous size even is the originality in its conception and mode of execution, the result of which has been a structure of great stability and comparatively small cost. Popular accounts of the work have appeared in various publications during its progress and since its completion; but there are various scientific aspects of the undertaking which have not been adequately described. The present article will refer to such technical details as may be of value to those who study the application of scientific principles to industrial ends.

The new methods employed in the construction of the Tay Bridge cannot any longer be regarded as experiments. The severe tests imposed by the Government Inspector and by a heavy traffic uninterrupted during several months removed all uncertainty as to their success and make them of greater value. We may now therefore speak of the details of the structure, so far as these are based on scientific principles, with confidence, seeing that the trial of the bridge may now be regarded as conclusive.

The bridge consists of 85 spans varying in length from 27 to 245 feet. Beginning on the south side there are first 3 spans of 67 feet, then 2 of 88, then 10 of 130, then 13 of 145, 13 of 245, 1 of 162, 11 of 130, 25 of 69, 1 of 170, and 6 of 27 feet. The direction of the approaches on both sides made it necessary to introduce a curve of 1,320 feet radius at each end of the bridge; that on the north side extending over 88°, and that on the south over 16° 30′, the central part of the bridge, 7,960 feet long, being straight. Of the thirteen 245 feet spans, 7 are level, and placed so high that they offer a clear water-way of 88 feet at high water. From these northwards, a slope of 1 in 73 brings the structure to the required height to join the land line, while southward an incline of 1 in 365 serves the same purpose. In order to gain as much clear height as possible in the channel used for navigation, the roadway is laid on the bottom of these large spans, the trains running between the girders, while on the other parts of the bridge, with the exception of the 170-feet span on the north side, the sleepers are fastened on the top of the main girders.

Nature of the River and its Bottom.

The Tay is a tidal river about two miles wide at the site of the bridge. The rise and fall of the tide in ordinary spring tides amounts to about 15 feet, but local circumstances affect this height to a great extent, the difference between the observed and the computed heights sometimes amounting to 3 feet. The strength of current is about five knots per hour. Fig. 1 shows the depth of the water and the nature of the river bottom. The greatest depth is found between piers 15 and 20, but a bank a short distance above the bridge closes up what otherwise would be the best channel for navigation. The rocks on both sides consist of trap. At the south side they rise abruptly to a height of 53 feet, the base being washed by the flood-tide. The river bed to 100 yards out from the south shore is composed of gravel overlaying blue clay with beds of peat and large layers of decayed hazel nuts which at one time grew in abundance near the site of the bridge. Further out the gravel gets coarser, and boulders are found on the river bottom. The trap rock disappears at pier 5, and its place is taken by red sandstone with a rather worn surface. At pier 20 the surface soil consists of sand, and continues to do so to within a few yards of the north side of the river. The sandstone has a northerly dip increasing at pier 15, and from this point northward to pier 78 rock is not any longer found at a depth which makes it available for foundation.

The old river-bed, consisting of gravel and clay, continues, however, almost level along the whole line of the bridge. The sand overlaying it is very sharp and pure and contains a large number of shells. Underneath the gravel is a mixture of sand and clay. From pier 70 northward layers of peat and decayed wood are often found in the sand.

Plan for the Foundations.

The following plan was followed for the foundations:—From pier No. 1 to No. 14 the rock had to be reached, the weight per square foot of surface amounting to eight tons. Piers No. 15 to No. 19 consist of a caisson sunk only a few feet into the bottom, and then piled, each pile having to carry a weight of twenty-five tons. Piers No. 20 to No. 80 are founded on the gravel layer, the pressure per square foot being about two tons. Thence to the north shore the piers rest again on rock.

General Description of Piers.

Before describing the *modus operandi* adopted in building the bridge it will be well to give a short description of the piers. The first three commencing from the south side have a rectangular section. At the base they are 14 feet 6 inches by 7 feet 6 inches, and at the top 11 feet 6 inches by 4 feet 6 inches. The clay is excavated at low water, and the rock levelled. A concrete foundation is put in, and on these the piers are erected solid in brick and cement. On the top they have a cope of stone 15 inches in thickness, and on this rest the bed plates and girders. For piers No. 4 to No. 14 two cylinders having at the base a diameter of 9 feet 6 inches are placed at a distance of 12 feet, centre to centre, and connected by a web wall 2 feet 6 inches thick. Under water they consist of brick tubes surrounded by a cast-iron casing 1 inch thick, the centre of each cylinder and the common base being filled up with concrete. Above water the diameter is 8 feet 6 inches below and 6 feet 6 inches on the top, and they are finished off with a course of stone in the same manner as the first three. From piers Nos. 15 to 58 the work above high water consists of iron columns varying in diameter from 12 to 20 inches, and having a thickness of metal of 1 inch. These are braced together by horizontal and diagonal bracings and filled with cement to prevent interior corrosion. In the under water work they differ widely according to the nature of the river bottom and the weight they have to sustain. For those from 15 to 19 a malleable iron caisson 10 feet high, oval in shape with a major axis of 23 feet, and a minor axis of 16 feet is provided with a lining of brick-work 9 inches thick and sunk a few feet into the river bottom. Forty piles are then driven inside as far as a one-ton ram falling from a height of 10 feet will drive them. The depth to which they penetrate varies from 15 to 20 feet. These piles are cut off 3 feet above the ground, and the caisson is filled up level with concrete. On top of this concrete a hollow brick pier, hexagonal in shape, is placed, and the space inside up to low water is also filled with concrete. From low to high water the concrete is replaced by solid brickwork, and a course of stone brings the height of these piers to 5 feet above high water. Piers Nos. 20 to 27 are constructed by joining two 15-feet diameter cylinders above low water, after sinking them through the sand to the gravel bed. They are then carried up in the same manner as described for 15 to 19. The fourteen piers supporting the thirteen large spans have a 31-feet malleable iron cylinder with a lining of brickwork 14 inches thick, and are sunk to the gravel layer, and of such height that after reaching the solid bottom their top is slightly projecting above the river bottom. They are then filled in with concrete, and a brick block corresponding in shape with those used for the other piers, but of greater dimensions,

measuring 27 feet in the longest, and 16 feet in the transverse direction, is put on the foundation, filled with concrete, and carried up solid to high water, where it has a cope 5 feet thick. For the 162 and 130 feet spans on the north side the construction is similar to that adopted for piers 20 and 27, while the shorter spans in

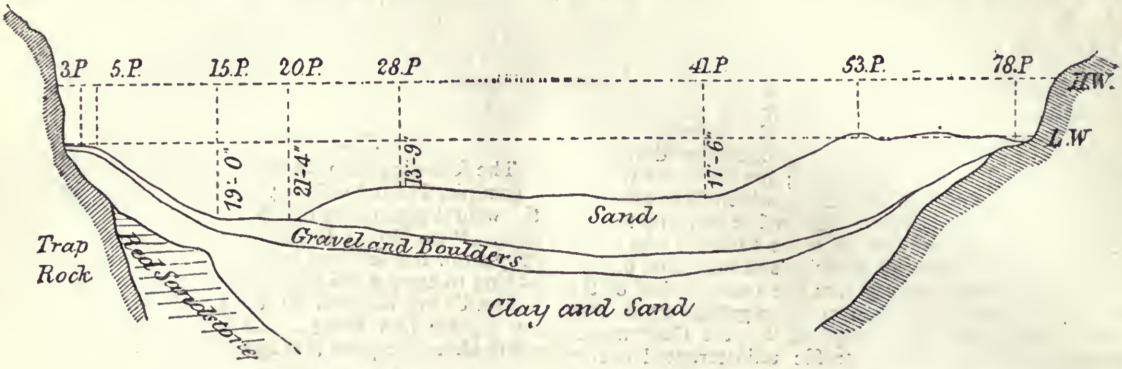

FIG. 1.—Section of river. Horizontal scale 2,000 feet to 1 inch. Vertical scale 50 feet to 1 inch.

the curve are supported by columns set in 6-feet cylinders sunk to the required depth and filled up with concrete.

No Staging to be Used in the Construction.

The change in the nature of the river bottom, the great height at which the bridge had to be constructed and the heavy gales which are prevalent in this part of the country made it necessary from the beginning to depart from the rules generally laid down for the construction of such works. The erection of scaffolding and staging was by these circumstances rendered impossible; and a series of operations were substituted for these old methods which by their success proved to be great improvements, and must have great interest to engineers and others less directly connected with such

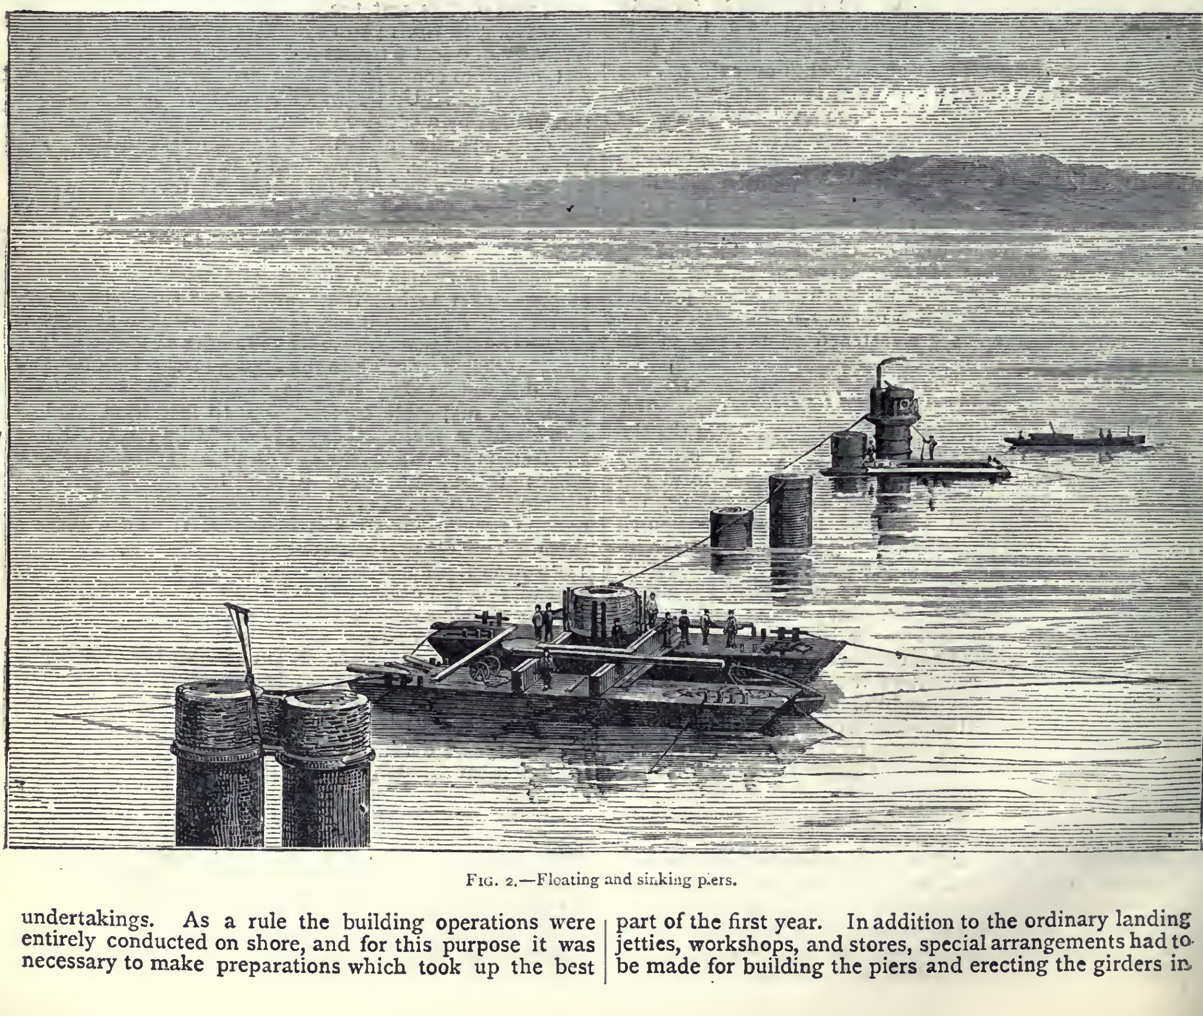

FIG. 2.—Floating and sinking piers.

undertakings. As a rule the building operations were entirely conducted on shore, and for this purpose it was necessary to make preparations which took up the best part of the first year. In addition to the ordinary landing jetties, workshops, and stores, special arrangements had to be made for building the piers and erecting the girders in

such a manner that they could be transported to their permanent places without great difficulty. Level foundations of concrete and stone were constructed on the foreshore, some of which were used to put together and rivet the iron caissons forming the outer shell of the piers, others to build the brick work for that part of the piers between the river bottom and low water.

Building and Floating the 9-feet 6-inch Cylinders.

After the caissons had been put together and the brickwork built in, they were floated between barges to the point where they had finally to form part of the structure.

The apparatus employed for lifting them consisted of a system of iron girders resting on barges. Flat bars or links having 2″ holes 12″ apart, connected the base of the piers with hydraulic rams placed on these girders. The weight could either be taken on the girders direct or on the rams. At high water the girders were floated over the top of the piers, and after the tide had receded, and the base was accessible, the connection between the lifting links and the base of the cylinder was made. As the tide rose again it lifted the barges, and with them the pier, hanging between them off its resting-place, when it could without difficulty be towed to its destination, where previously moorings had been prepared for it. For this operation it was of course necessary to have a tolerably calm day, and as the weather in the Tay is subject to very

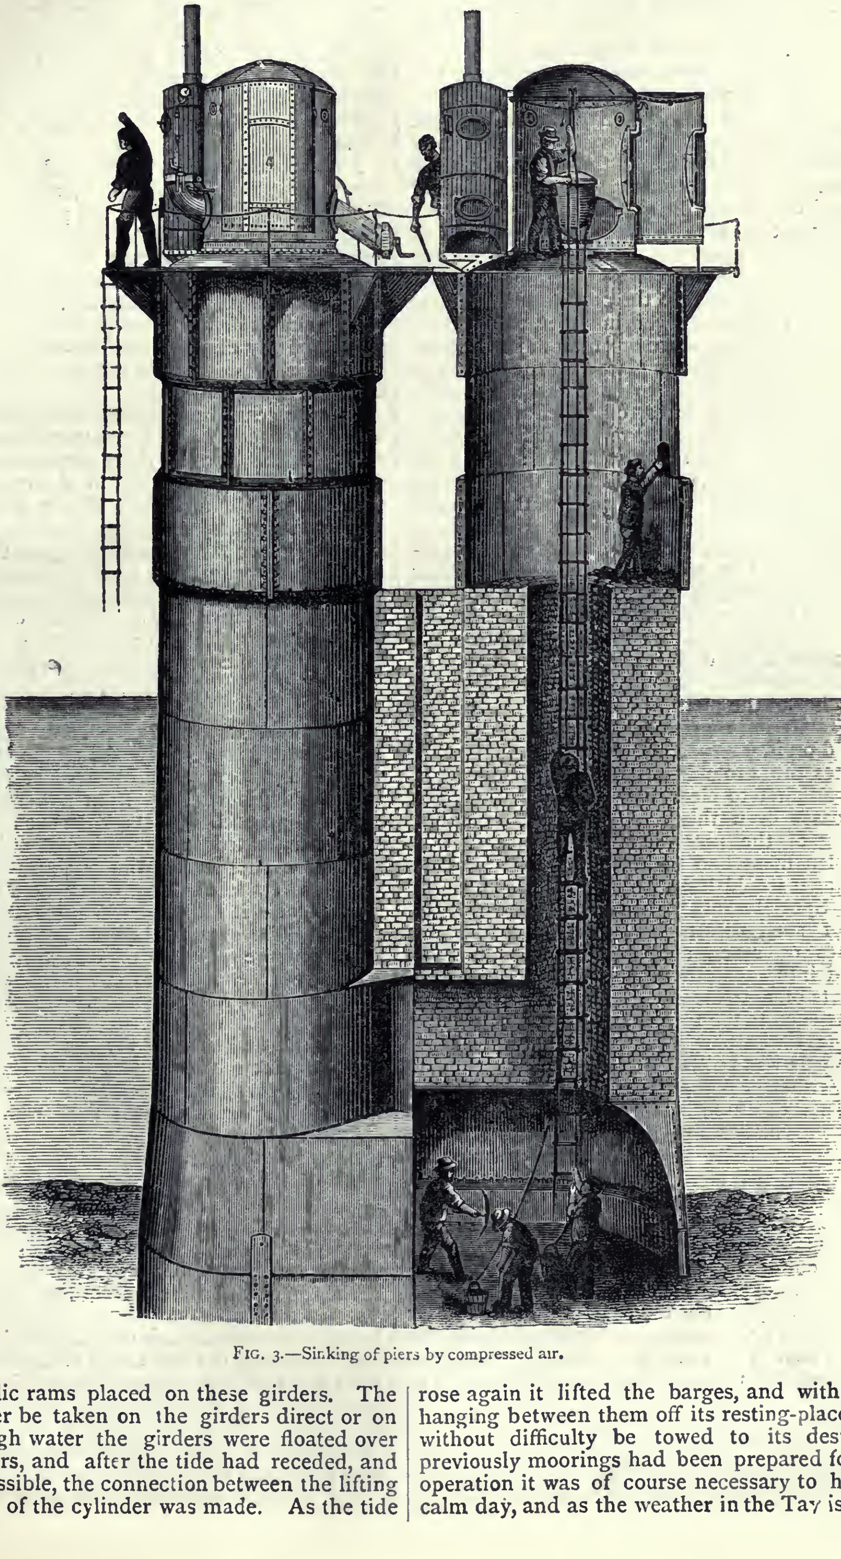

FIG. 3.—Sinking of piers by compressed air.

rapid changes, the operation was sometimes interrupted and frequently endangered by sudden gales, it becoming necessary to take the piers away from the place where it was intended to lower them, and as they could not be placed back in the same position they had to be taken to Dundee Harbour for shelter. The weight of these piers was about 100 tons, and the carrying barges were 60 feet long by 12 feet wide, and 6 feet deep. If the weather continued favourable, the work of lowering took place the same tide. For this purpose the rams were pumped up 12″ while the weight was on the steel pins resting on top of the girders. The connection between the rams and the links was then made, whereupon a few additional strokes relieved the lower pins of the weight, so that they could be withdrawn and inserted in the next hole. By allowing the water to leave the rams, the pier would of course be lowered till the weight came again on the lower pins, after which matters were in the same position as at the beginning, and the operation could be repeated, and the pier lowered foot by foot.

No great attention was paid to the position of the pier till it neared the river bottom. Then, however, an observer with a theodolite placed on shore or on an adjacent pier, directed the men at the capstans placed on the barges to draw them to such a position as to have the pier exactly in line, while double steel wires, of which the length had been carefully determined, gave the distance from the pier previously placed in position. As soon as the position was in every respect satisfactory the lowering was proceeded with quickly, and it became in this manner possible to put a pier very nearly in its right place. Especially in the curve this work required great attention and care, but it has admirably succeeded. After disconnecting the links which joined the lifting girders to the piers the rising tide would float these with the barges over the top, leaving the cylinder standing on the river bottom. Fig. 2 shows one of these cylinders moored in the river and the general arrangements for floating and lowering. Another of the piers is ready to 5′ above high water, and others are in progress. One has the pneumatic apparatus placed on it.

In most cases the ground was sufficiently level, in others divers had first to clear the bottom of boulders, and in three cases even this was not found effectual, and the settling of the pier on one side caused it to upset. The fallen mass had to be lifted out of the road and broken up as it would have been too costly to set it on end again. Special struts to prevent the possibility of a recurrence of such disasters were then introduced. Two iron tubes of seven and eight inches diameter respectively slid into each other by means of a stuffing-box like the parts of a telescope. The upper end of the top part was fastened to the top of the pier and connected with a pump, the lower part had a mushroom-like base, and when this part was pulled away from the pier under an angle and then water pumped in it took a firm hold in the ground. Four of these struts applied to each pier held it perfectly in position as long as the water pressure was not withdrawn from them. In the subsequent operation of sinking the pier the cocks giving egress to the water were left open, and as long as the motion of the pier was a vertical one the water would escape from all four struts in a gentle flow. As soon, however, as the pier went out of the perpendicular the strut on that side would eject a stronger stream of water, and the man in attendance had only to shut the cock pertaining to that strut to make it answer its purpose of supporting the pier on the side to which it was inclined to fall. This apparatus fully answered the purpose for which it was constructed.

Sinking by the Pneumatic Process.

In order to sink the piers through the layer of clay overlying the rock the pneumatic process was employed. Temporary castings were added to the top of the pier bringing the latter above the highest water, and a malleable iron air-bell, having the usual air-lock for the passage of the workmen, and smaller locks for the passage of excavating material to the outside or concrete to the inside was placed on the top (Fig. 3). A six horse-power steam-engine, connected with an air-pump, supplied the air by the pressure of which the bottom of the pier was kept dry. The breathing of the men and the burning of candles required, of course, a more liberal supply than would have been necessary for the first purpose only. Instead of allowing this surplus to escape at the bottom of the pier it was used to drive a pneumatic hoist lifting the excavated materials up to the air-lock.

As the excavations proceeded, the pier would sink down till it reached the rock, and this movement was facilitated by the bottom of the pier being slightly conical. The rock was then levelled down by pick-axes and chisels so as to give a firm bearing, and concrete material introduced filling up the bottom chamber and the shafts which had been left in the brick-work for the passage of the men. When this work had proceeded to above low-water, the temporary castings and air-bells were removed and the pier built up between low and high water in the usual manner from a barge.

This process, though slow and costly, worked on the whole satisfactorily, so far as the piers were founded upon rock. It was carried through without many accidents, though one occurred in which six men unfortunately lost their lives. On a stormy day in August, 1873, a barge loaded with coals, moored near one of the piers in process of sinking, probably knocked against the structure and must have damaged the iron—though it was not observed at the time—to such an extent that at the next high tide, when the air pressure was greatest, one of the top plates was blown out, the water rushing in from both top and bottom, and of course making escape an impossibility.

Piled Piers.

The oval caissons for piers Nos. 16 to 19, were built, and floated out in precisely the same manner, and then excavated under water by a diver (the excavated substance being hoisted up from a barge) and sunk 2 feet into the ground. A staging constructed of angle iron was then floated out and put over this caisson, and was used as a support for the pile driver. The piles had a length of 60 feet. The depth at the highest tide was 45 feet, and it was therefore possible to drive them 15 feet into the ground, before any means of lengthening them for the purpose of driving, had to be adopted. Divers were engaged to cut them under water, leaving 3 feet standing in the caisson. Concrete lowered in large buckets, which only opened when getting to the bottom, surrounded and covered the heads of the piles, the height of the concrete being 7 feet above these heads. During all these operations the caisson extended temporarily to above high water, so that the diver could continue his operations during the whole of the tide, notwithstanding the strong current, and the danger of washing the essential parts of the concrete away was considerably lessened. An inspection, undertaken for the purpose of ascertaining how far the latter had been successful, gave very satisfactory results, the whole mass of the concrete being found perfectly hard after a few days. The disconnection of the temporary caisson from the lower part, and floating away in the same manner as that by which it had been brought out was a work of little difficulty.

The floating out and fixing of the brick pier which was put on top of this concrete foundation will be described more fully with the operations necessary to complete the large piers. These are certainly the most interesting ones on account of their magnitude, although this very size may have been the means of avoiding particular difficulties which stood in the way of the work connected with the

smaller piers. It has been found throughout the operations that in a river subject to such vicissitudes as the Tay, the handling of a very heavy mass is a far less intricate and difficult matter than that of lighter weights, and during the execution of the work connected with the larger spans the operations were not in the least interrupted by weather which would have been absolutely fatal to the smaller piers.

Work on the 245-feet Span Piers.

The under-water work of the large piers can be conveniently divided into three parts: that of building, floating, and sinking the caisson; that of building, floating, and fixing the brick pier; and that of bringing it up to the required height five feet above high water. The first two are, of course, by far the most important. The lower caisson consisted of $\frac{5}{8}$ inch malleable iron plates riveted together so as to form 31 feet cylinders 20 feet high. After erecting this structure on the foundation on the foreshore prepared for it, a lining of brickwork 14 inches thick was built inside. This lower part was to form part of the permanent structure. On top of it and connected with it by a bolted horizontal joint, another length of plates was built bringing the whole up to 40 or 44 feet of height, according to the depth of water. This top part merely served a temporary purpose, and in order to resist the effect of the waves and current it was provided with angle iron stiffeners to a far greater extent than the permanent part, which derived sufficient stiffness from its lining of brickwork.

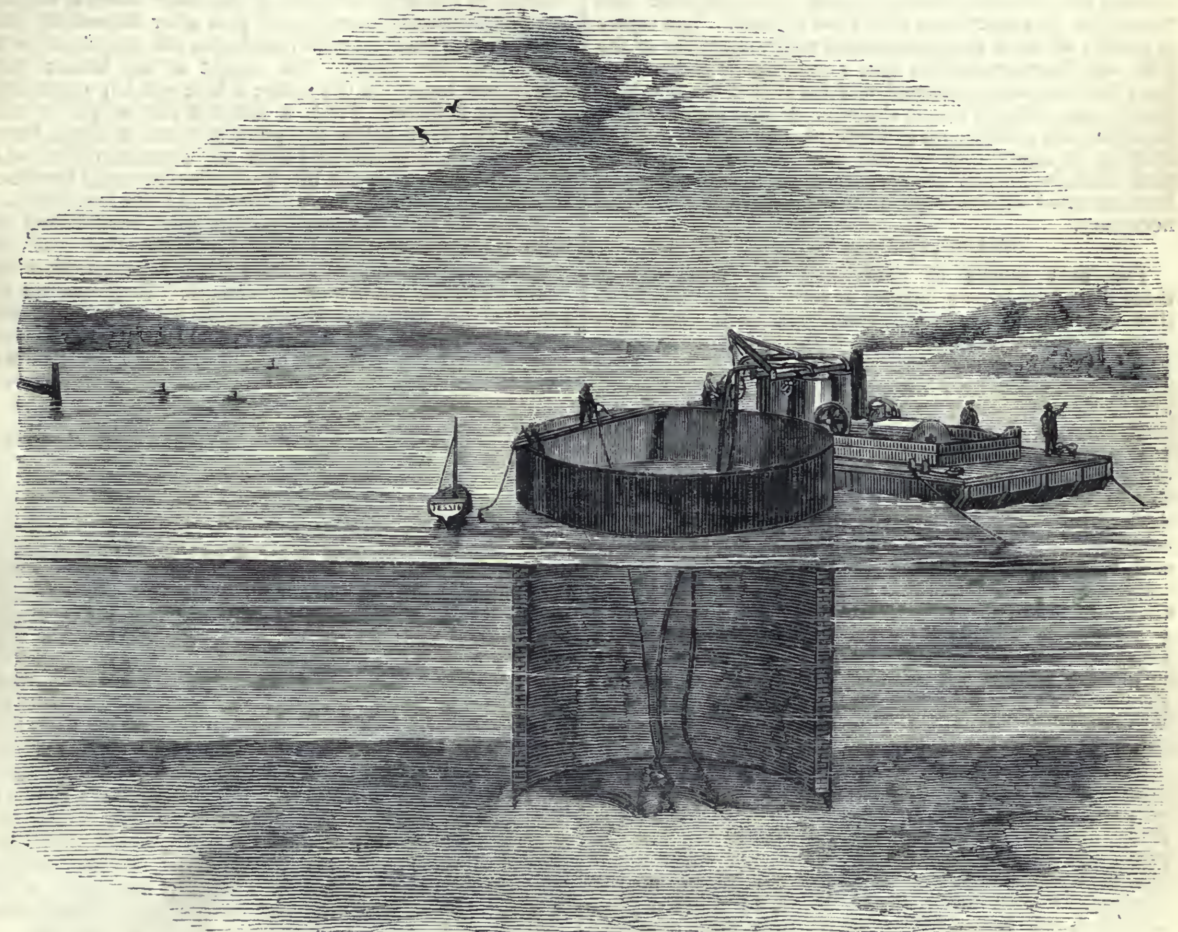

FIG. 4.—Sinking of large caissons.

At four points of the circumference T iron strips ran vertical from top to bottom, and were riveted to the caisson. In these strips or links there occurred three and a quarter inch holes at intervals of 1 foot, and by putting steel pins of slightly smaller diameter through these holes, it became possible to obtain a hold with the hydraulic rams by means of a girder with a claw-like end placed on their tops. The hydraulic rams were placed on the four corners of a square system of girders having projecting ends for the barges. On the under-side of these girders a claw similar to that found on the top of the rams made it possible to take the weight of the pier either on the four lower claws, or the four top claws, which were connected with the hydraulic rams.

Two pontoons, each 70 feet long, 20 feet wide, and 7 feet deep, lifted the weight of girders and the piers standing in between them off the ground by means of the lower claw. It was then floated out; and so powerful was the resistance which the heavy mass, weighing about 200 tons, offered to the current, that two strong tug steamers had to be employed for this purpose. Arrived at its destination, it was securely moored. The first one floated in this manner had to withstand the fury of a three days' gale, during which it had to be left out in the river, the waves washing right over the barges, the hatchways having been nailed and caulked to keep the water out.

To lower the caisson the rams were pumped up 12 inches and the steel pin which connected the upper claw

with the caisson inserted. By pumping up again the weight was taken off the lower claw, the pin which had held it there withdrawn and inserted in the hole a foot higher up. The water was then allowed to flow out of the rams and the weight to come down on the lower pin again, during which operation the caisson had necessarily been 12 inches lowered. The work of adjusting it in its right place was accomplished in the same manner as described for the smaller piers. The first of these caissons was lowered down on August 28, 1875, and the same afternoon the floating girders and barges were withdrawn, and the pier left standing on the sandy bottom. The tide was particularly strong, and from the resistance which this mass offered to its flow washed away the sand round about it, thereby causing the pier to heel over to such an extent that next morning it was more than 6 feet out of level. The centre of gravity of these piers, compared to the diameter of the base was, however, so low that no serious apprehensions were felt, and when the sand was excavated on the high side it soon came to the level again. It was always found possible with a little care to keep the pier nearly level in sinking by excavating on one side or another, and no such artificial means of keeping them upright, as had been adopted in the case of the smaller piers, became necessary.

Sinking the Large Caissons.

The best means of excavating the sand out of these piers had been a subject of very careful consideration, and numerous experiments had been tried with varying results, in order to find the best machinery for effecting that purpose. Finally, however, an apparatus constructed upon very simple principles by Mr. Reeves, one of the contractor's assistant engineers, was found the most efficient. The conditions which it had to fulfil were of this kind. It had to elevate the sand from the inside of the cylinder and drop it outside at a small cost, and it had to be constructed in such a manner as to be easily detached from the pier in case of a sudden gale. These conditions were fulfilled by placing the whole apparatus on a barge which could be moored alongside the pier and withdrawn with little trouble and at a moment's notice. On this barge were placed four air-tight tanks each having a circular hole in the bottom, closed by a door on which an india-rubber ring was fastened so as to obtain an air-tight closing. A steam-engine worked two exhaust air-pumps, and each of these pumps was so connected with two of the tanks that by means of a three-way cock either the one or the other could be put in communication with it. From the top of the tanks flexible pipes of 4 inches diameter ran down to the bottom of the pier, and their ends were in charge of the diver, who could direct them. Either of these tanks being put in communication with the pump would be exhausted, and a current of water mixed with sand would rush up the flexible hose, filling up the vacancy. A float indicated the height to which a tank was filled, and before any water or sand could enter the air-pipe and reach the valves, the attendant had to turn the cock which brought the other tank into communication with the exhaust-pump and admitted air into the full one. It then discharged its contents through a hole in the bottom of the barge into the river. The joints of the cylinder not being water-tight, the level of the water inside was always as high as that outside, and the only purpose of the temporary caisson was to protect the divers from the strong current, and give those in charge of the operation an opportunity of observing the position of the pier during its descent. Fig. 4 shows this apparatus at work by one of the large piers.

Building the Brick part of the Pier.

It will be understood that by the sinking of this caisson a hole was formed in the sand, the sides of which were kept up vertically by the caisson while the bottom was formed by the hard gravel layer. This pit was now filled with concrete to a couple of feet above the river bottom, and all the iron above that point removed. The concrete hardening became like a rock with a level surface of 31 feet diameter. The remaining part of the pier up to high water consisted of brickwork only. The lower portion was built on a level part of the foreshore in bricks and Portland cement, which became so hard that the block could be lifted from four points by means of barges and apparatus similar in all but the dimensions to that used for the floating of the 9′ 6″ piers. Previous to the building a layer of paper was spread on the temporary foundation in order to prevent the brickwork from adhering to it. The block was hexagonal in shape, measuring 27 feet in one direction and 16 feet in the other. Its height would depend on the depth of water at the place where it was to be used, and was so regulated that after depositing the block on the artificial rock foundation the top would be a little above low water. The weight of the blocks was about 200 tons. In the centre a hole was left answering a double purpose. First, it allowed the weight of the block to be kept below the point at which it would have become unmanageable and than the concrete which was put in this hole after the block was *in situ* would increase the adhesion between the brickwork and the foundation.

From low to high water line the pier was finished in solid brickwork set in Portland cement, the work of course being interrupted at every rising tide and taken up again when the water was low enough. Four courses of ashlar of an aggregate thickness of 5 feet brought the pier to the height at which the cast iron columns commenced and the bolts to hold down their bases were fixed in the stone.

Superstructure.

In the erection of the iron superstructure the same principle of not employing staging in the river was adhered to. The iron-work as it arrived, in pieces of from 20 to 35 feet long, from the contractor's works at Middlesborough, was landed on a jetty near the shore about 260 feet long, over which a strong travelling crane could be moved from end to end. Here the parts were put together and riveted up. All the girders with the exception of the 170-feet span and the 27-feet spans, are parallel lattice girders having diagonal struts and ties. The section of the booms is trough-shaped, that of the compression diagonals H-shaped, while the tension bars are flat, varying in thickness from three-eighths to five-eighths of an inch. Those girders which have the roadway on top have half struts running up from the intersections of the diagonals to the top boom, while those where the load is at the bottom have tie-bars for the same purpose. The depth of the 245 feet spans is 27 feet, their width 15 feet, and their weight about 190 tons. In them the rails are carried on longitudinal sleepers resting on iron cross-sleepers 5 feet apart, while in all the other spans wooden sleepers 3 feet apart, and having a section of 12 by 9 inches, carry the roadway.

Floating the Girders.

When a girder was completely erected and riveted up, parts of the jetty on which it rested were removed at each end, and barges were introduced at a low state of the rising tide in the gaps. As the height of the water increased these barges would touch the under-side of the girders, and a further rise would lift them off the bearings on which they had been erected, and keep them floating on the two pontoons. It will be seen that in order to get the ends of the girder free for depositing them on the piers, it was necessary to keep the barges at some distance from these ends and to introduce temporary vertical struts between those parts of top and bottom boom which rested on the barges. In addition to these struts some others were used to steady the comparatively high and narrow girders on their floating supports in case rough weather should

occur during the operation. For the different sizes of girders, different jettys and pontoons were used, but apart from this the operation was carried on in the same manner in all cases. But here again it soon became clear that while to carry out the smaller ones in doubtful weather was a dangerous operation, the larger ones were far less liable to disturbance by the weather, and some of them in fact were subjected to a severe trial in this respect, the two tugs on one occasion being unable to tow the structure in the ordinary manner against the strong westerly wind, and breaking all the tow ropes. As soon, however, as additional towing power had been procured, the operation was successfully carried through. Intricate as it seemed to build these heavy girders on shore and tow them to their destination—often more than a mile distant—by the use of plant specially designed for the purpose, the execution became very easy, it seldom taking more than twenty minutes to convey them from the one place to the other.

Lifting the Girders to their Permanent Resting Places.

The general arrangement of the six columns which have to support the larger spans follows that of the brick piers on which they rest. Four centre columns placed in a square and connected by strong vertical and diagonal bracing, are 15 inches in diameter, and from these centre columns the lifting of the span takes place. Each of the columns is about 10 feet long, varying slightly according to the height of the pier, and every second length has brackets cast on to which transverse girders are bolted. The outside columns placed on the point of the pier are 18 inches diameter, and as well as the inside ones 1 inch thick. Between these outside and inside columns rest the ends of the main girders, the end cross girder and end horizontal bracing having been left out so as not to come in the way of the four central columns and their bracings during the process of lifting. To each vertical end post a T strip is bolted from top to bottom in the same manner as was described for the large caissons. In common with these it has $3\frac{1}{2}$ inch holes at 12 inches distance. A transverse trough girder of slightly shorter length than the distance between these end posts is placed on the temporary girders connecting the columns, and in this two hydraulic rams, carrying another girder are fastened. By inserting steel pins in the holes nearest to this top girder, and then pumping up, the main span can be raised to such a height as the stroke of the rams will permit, and if at that point pins are put in the holes then nearest to the fixed or lower ram girder and the weight allowed to come down upon these, the rams can be lowered again without letting the main girders down, and by a shifting of the pins to a lower hole, the operation can be repeated, each stroke of the rams causing a rise of the girders of 1 foot. The motive power is derived from a pump worked by manual labour, the space at disposal not permitting the introduction of steam-power for this purpose. The diameter of the pump-plungers must therefore be small, and the movement of the rams consequently a slow one. It was, however, possible to lift 20 feet a day, and during the long days of summer a 40-feet lift has often been reached in 24 hours. Another set of apparatus was kept in readiness on the next lifting girder, and with it operations were continued, when the girder had become too high for the lower ones, which then in their turn were shifted to a higher point. As the girder rose, the bracings connecting the outer columns with the four central ones were put in, and after it had reached its final height a system of girders capable of carrying the bed plates and superstructure were fastened on the top of the columns, and the girder which had been elevated to a few inches above its proper height was lowered down on them. Before this could, however, be done, they had to be connected to the next set of girders, as they were calculated as continuous girders and joined together in sets of four. To make these junctions, one of the ends had to be lifted up from 5 to $6\frac{1}{2}$ inches, while the junction plates making the top and bottom booms continuous were riveted on. The lowering of the girder at the other end would then produce an initial strain in these junctions and fulfil the requirements of continuity. A good deal of time was required for making these junctions, the junction plates having all to be carefully marked and drilled while the girders were still hanging in the apparatus, and this circumstance in one case led to a disaster which caused great loss and delay. On February 3, 1877, while the work of joining the two southmost of the 245 feet spans was in preparation, a gale of unprecedented severity came down the valley of the Tay with such a fierceness and suddenness that it was even impossible to get near enough to the piers to take off the men who had been at work on them, and they were obliged to seek shelter on one of the adjacent girders which had not been raised. The wind continuing to blow in strong gusts produced violent vibrations in the unbraced ends of the girders and gradually shifted them to the edge of the lifting girders, causing one side to fall when the limit of stability was reached, breaking down the pier and precipitating the other girder in consequence. The fallen girders had to be lifted, cut up, and replaced by new ones, and the work was thereby materially delayed.

Lifting of the 145 *Spans.*

The lifting of the 145 spans was accomplished in a somewhat different manner. The hydraulic lifting apparatus was placed on the top of a temporary structure of timber fixed on the cast-iron piers, a few feet higher than the top boom of the girder would be after being raised, and long links with holes a foot apart reached to where the girder stood 5 feet above high water. These girders being so much lighter could be raised to the top in one day, but as the arrangement of the columns was somewhat different from that of the 245 feet piers (the girders resting on the four central columns), they were hoisted while fixed together by temporary transverse bracings, which kept them at a greater distance apart than they would finally be, and hoisting them up outside the columns altogether. It was therefore necessary to modify the apparatus to this extent that the girders, after disconnecting the temporary bracing, could be slung in and permanently braced.

The work in connection with this bridge was begun in the summer of 1871, the first stone of the land pier on the south side being laid on July 22 of that year. During the first three years, however, little progress was made, and the operations during that time must be considered as being more of an experimental nature. From August, 1875, however, the progress was very great, and as the managers and men gained experience, the erection of the structure was proceeded with at a vastly accelerated rate. New workshops, jetties, and appliances of various kinds were added, a foundry erected for the casting of columns, and in September, 1876, it was found necessary, in order to keep pace with the building of piers and erecting of girders on shore, to work night and day, and the contractor introduced for the first time in Scotland electric light for out-door work. Two lamps, each of 1,000 candle-power, the current for which was generated by Gramme machines, did excellent service. The lamps were placed at right angles to each other, and in this manner they lit up an area of 100 by 500 yards in such a way that every kind of work could be carried on uninterruptedly. This was of great importance for the floating out of piers and girders which had to be done at high water, the preparations commencing three or four hours beforehand, and therefore having sometimes to be made in the early morning. The last pier was in this manner floated out at seven o'clock on the morning of December 26, 1876.

The bridge was severely tested by Gen. Hutchinson, the Government Inspector of Railways, in February of this year. Five locomotive engines of 72 tons weight each were placed on the large spans and run over them at considerable speed. This weight of 360 tons for each of the 245′ spans will never be reached in the working of the railway, 162 tons being the greatest load resulting on each span from the heaviest goods train. Under the test load the deflection of any of the spans did not exceed the calculated limit, and the lateral movement during the passage of trains was but trifling.

On June 1 the bridge was opened for ordinary traffic, and it is now daily crossed by numerous and heavy trains. For the North British Railway Company and the travelling public its completion is of very great importance. But the work must have a still greater importance in the eyes of engineers and those interested in the practical application of scientific principles, as many new methods to overcome formidable difficulties were successfully carried out, some of which might with advantage be used in similar structures. A. GROTHE

THE NORWEGIAN NORTH ATLANTIC EXPEDITION

THE expedition left Bergen on June 15, and proceeded without interruption to the Westfjord, in Nordland, where we had our first station. A temperature-series was here taken with Negretti and Zambra's new deep-sea thermometer, which showed 10°·7 C. on the surface, a minimum of 4°·4 in a depth of 40 fathoms, and 6°·5 at the bottom in 340 fathoms. The *Vöringen* stopped some hours at Tromsö to take on board a pilot, and proceeded to the Altenfjord, where we found 7°·3 at the surface, a minimum of 2°·7 in a depth of 100 fathoms, and 3°·9 in 220 fathoms at bottom. From Alten we went to Hammerfest, where we stayed two days. Our next stations were in the Porsangerfjord and in the Tanafjord. On all these stations we dredged and trawled with good success. On June 26 we were lying at Wardö, where Capt. Wille made magnetical observations of force and inclination. The declination was determined the day before off the coast by going round with the ship, and taking bearings of the sun on different courses. On June 27 we put to sea on an eastward course. The barometer was falling rapidly, and at midnight the wind and sea got so heavy, that the ship was put with the stem against the wind, and we were lying almost still. This situation lasted till the next night, when we again proceeded on our course, but very slowly, the ship pitching heavily, and the wind being constantly ahead. In this manner we found 0° C. at the sea bottom, in about 71° 30′ N. and 36° 30′ E. from Greenwich. We then sailed northwards and westwards, and passed the said bottom temperature several times, so that I am now able to give its situation pretty accurately in the chart. The northern part of this zero line forms a bay east of Bear (Cherry) Island, where the warmer water reaches a higher latitude, and runs close to the east side of that island, where we for the first time observed the polar ice. The temperature-series showed the accuracy of Weyprecht's observations, that the colder Polar water edges itself along the bottom from the east and north, and the warm Atlantic water runs out in a similar edge in the contrary direction towards Novaya Zemlya and Franz-Joseph Land. On July 4 we were at Bear Island, on the south-east side. We were happy to find the sky almost perfectly clear, a rather rare occurrence on this island. The ship was anchored outside the open coast, and we went on shore at the mouth of a little river, in the vicinity of which there stands a hut, which has been the abode of wintering parties. Here we deposited the mail which we brought for the Dutch polar expedition in the *Wilhem Barentz* schooner. The place was marked with a flag, and the letters, &c., dug down, inclosed in an outer wooden and an inner sheet-iron soldered box. I took a tour upon the nearest hills, collected some rock specimens, and measured the altitude of the highest peak on Bear Island, Mount Misery. The calculation gave me a height of 1,787 English feet, a result which I regard as very accurate. After dinner we weighed and proceeded to the south-west; crossed, the following day, the zero line of bottom temperature on the bank between Bear Island and Norway, sounded in 1,024 fathoms on July 6 in lat. 73° 6′ N., long. 11° 56′ E.; we went then east-south-eastwards, crossed again the zero temperature line, and shaped our course for Hammerfest, where we arrived on the 8th. The ship is now cleaned; we take in coal, and expect to be ready to sail on a westward cruise in three days. Our first cruise has yielded thirty-eight soundings, seventeen temperature series, ten dredgings, and seven trawlings, all successful. New species of animals have been found by our zoologists. Negretti and Zambra's newest reversible deep-sea thermometer has done us great service; the instrument has, almost without exception, worked very well. I have constantly compared its readings from the bottom with the reading of the Casella, Buchanan's improved form, and found a very close agreement. As I supposed, the wooden box which carries the thermometer gets water-soaked after a few experiments in a few hundred fathoms, so that it no longer floats, but this is no drawback, as the lead rushes down so fast that the thermometer always keeps its upright situation till it reaches the bottom, and it never requires more than three minutes for a perfect accommodiation to 0·1 of a degree. I therefore regard this instrument as a very important improvement, and feel much obliged to the inventors and makers.

Hammerfest, July 10 H. MOHN

THE TASIMETER

MR. EDISON has applied the principle of his carbon telephone to a new instrument which is said to be a measurer of infinitesimal pressure. The principle is the variation of the electric resistance of a carbon button due to variation of pressure, and the instrument is said to be an extremely delicate thermoscope. We have not yet, however, received any authentic account of its performance or of its accuracy, but its ingenuity certainly deserves a description, for which we are indebted to the *Scientific American*.

It is the outcome of Mr. Edison's carbon telephone. Having experimented with diaphragms of various thicknesses, he ascertained that the best results were secured by using the thicker diaphragms. At this stage, however, he experienced a new difficulty. So sensitive was the carbon button to changes of condition, that the expansion of the rubber telephone handle rendered the instrument inarticulate, and finally inoperative. Iron handles were substituted with a similar result, but with the additional feature of musical and creaky tones distinctly audible in the receiving instrument. These sounds Mr. Edison attributed to the movement of the molecules of iron among themselves during expansion. He calls them "molecular music." To avoid these disturbances in the telephone, the handle was dispensed with; but it had done a great service in revealing the extreme sensitiveness of the carbon button, and this discovery opened the way for the invention of the new and wonderful instrument.

The micro-tasimeter is represented in perspective in Figs. 1 and 2, in section in Fig. 3, and the plan upon which it is arranged in the electric circuit is shown in Fig. 4.

The instrument consists essentially of a rigid iron frame for holding the carbon button, which is placed between

two platinum surfaces, one of which is fixed and the other movable, and in a device for holding the object to be tested, so that the pressure resulting from the expansion of the object acts upon the carbon button.

Two stout posts A, B, project from the rigid base piece, C. A vulcanite disc, D, is secured to the post, A, by the platinum-headed screw, E, the head of which rests in the bottom of a shallow circular cavity in the centre of the disc. In this cavity, and in contact with the head of the screw, E, the carbon button, F, is placed. Upon the outer face of the button there is a disc of platinum foil, which is in electrical communication with the battery. A metallic

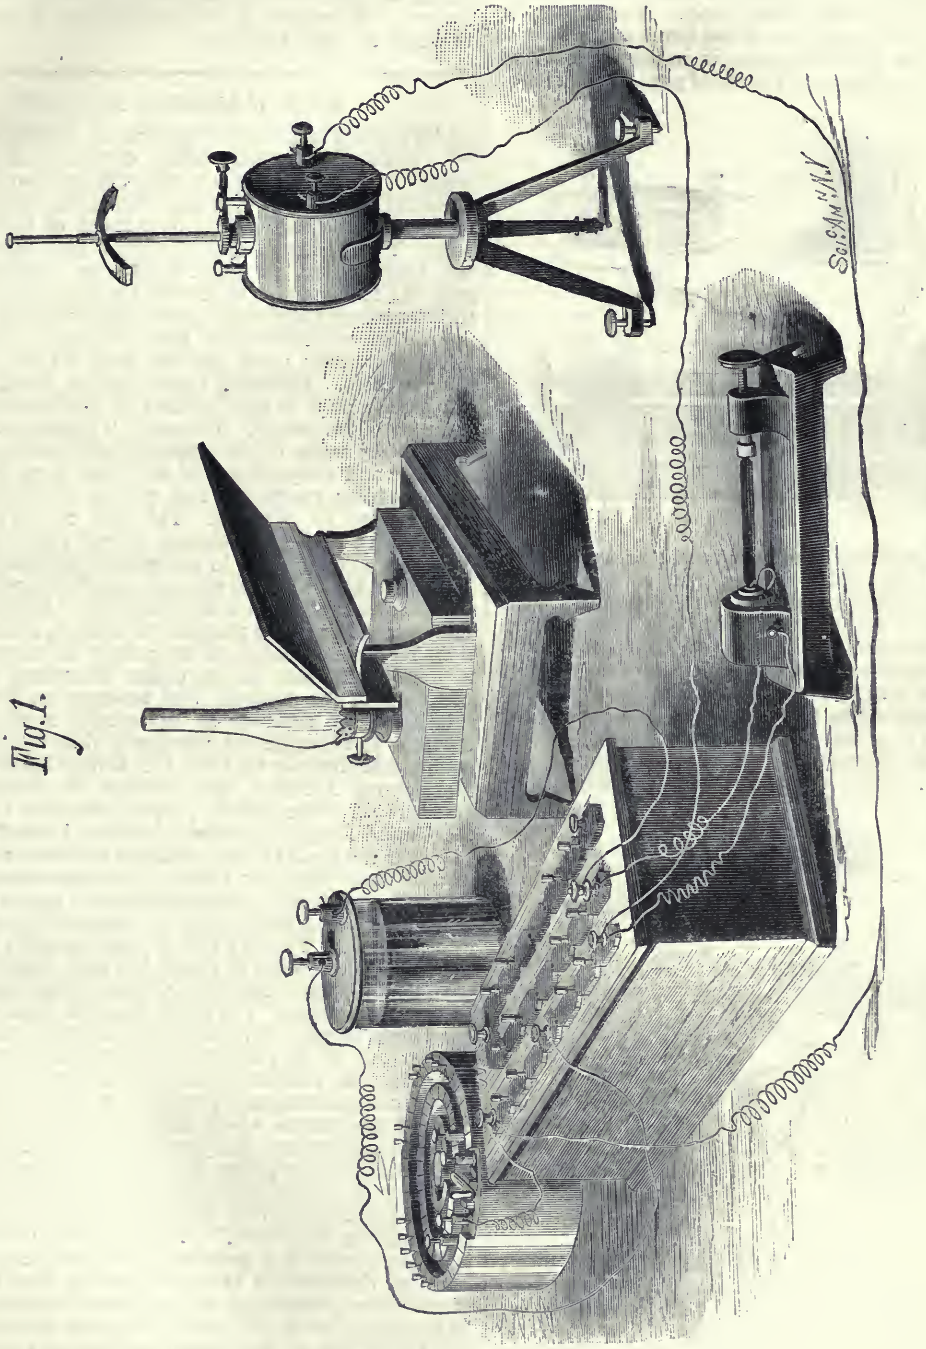

Fig. 1.

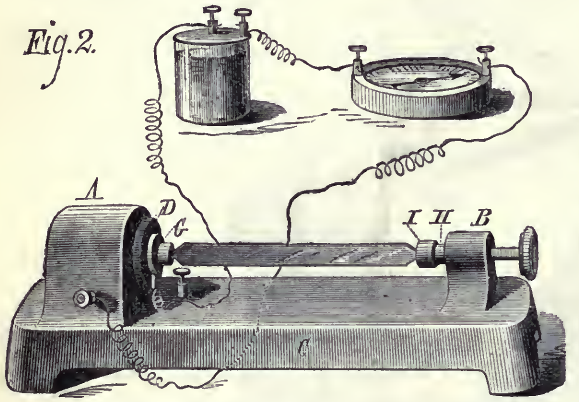
EDISON'S MICRO-TASIMETER.

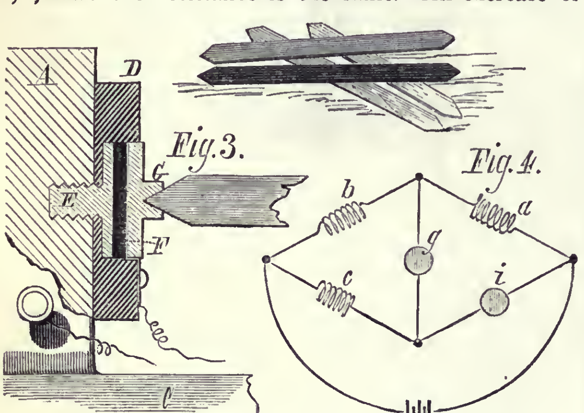
cup, G, is placed in contact with the platinum disc to receive one end of the strip of whatever material is employed to operate the instrument.

The post, B, is about four inches from the post, A, and contains a screw-acted follower, H, that carries a cup, I, between which and the cup, G, is placed a strip of any substance whose expansibility it is desired to exhibit. The post, A, is in electrical communication with a galvanometer, and the galvanometer is connected with the battery. The strip of the substance to be tested is put under a small initial pressure, which deflects the galvanometer needle a few degrees from the neutral point. When the needle comes to rest its position is noted. The slightest subsequent expansion or contraction of the strip will be

indicated by the movement of the galvanometer needle. A thin strip of hard rubber, placed in the instrument, exhibits extreme sensitiveness, being expanded by heat from the hand, so as to move through several degrees the needle of a very ordinary galvanometer, which is not affected in the slightest degree by a thermopile facing and near a red-hot iron. The hand, in this experiment, is held a few inches from the rubber strip. A strip of mica is sensibly affected by the heat of the hand, and a strip of gelatin, placed in the instrument, is instantly expanded by moisture from a dampened piece of paper held two or three inches away.



For these experiments the instrument is arranged as in Fig. 2, but for more delicate operations it is connected with a Thomson's reflecting galvanometer, and the current is regulated by a Wheatstone's bridge and a rheostat, so that the resistance on both sides of the galvanometer is equal, and the light-pencil from the reflector falls on 0° of the scale. This arrangement is shown in Fig. 1, and the principle is illustrated by the diagram, Fig. 4. Here the galvanometer is at *g*, and the instrument which is at *i* is adjusted, say, for example, to ten ohms resistance. At *a*, *b*, and *c* the resistance is the same. An increase or



diminution of the pressure on the carbon button by an infinitesimal expansion or contraction of the substance under test is indicated on the scale of the galvanometer.

The carbon button may be compared to a valve, for when it is compressed in the slightest degree its electrical conductivity is increased, and when it is allowed to expand it partly loses its conducting power.

The heat from the hand held six or eight inches from a strip of vulcanite placed in the instrument—when arranged as last described—is sufficient to deflect the galvanometer mirror so as to throw the light-beam completely off the scale. A cold body placed near the vulcanite strip will carry the light-beam in the opposite direction.

Pressure that is inappreciable and undiscoverable by other means is distinctly indicated by this instrument.

Mr. Edison proposes to make application of the principle of this instrument to numberless purposes, among which are delicate thermometers, barometers, and hygrometers. He expects to indicate the heat of the stars and to weigh the light of the sun.

KEW GARDENS REPORT

SIR JOSEPH HOOKER'S Annual Report for 1877 is more than usually bulky, extending to fifty-three pages. The report opens with the number of visitors admitted to the gardens during the year, which amounted to 687,972, a great excess over those of the preceding year. The points of public interest first treated of by the Director are, as might have been supposed, those affecting the agitation to remove the boundary wall along the Richmond Road and to open the gardens at an earlier hour. These points have been so freely discussed of late in the public press that we need do no more than refer to them. Referring to his visit to North America, Sir Joseph pays a high tribute to the intelligence and courtesy of the people. He says: "I cannot adequately express my sense of the liberality with which travelling facilities and hospitalities of all kinds were accorded to me by public companies and private individuals wherever I went in America. The fact of my being connected with this establishment [Kew] was a recognised passport, and this even in the remote settlements of the Far West, for I found a reading people everywhere, few of whom had not heard of Kew Gardens. In the Northern States of America the progress of science, and of institutions for the instruction of the people in science, occupy a prominent place in the cheap illustrated periodical literature of the masses; and nowhere on the globe is this literature better or so universally read as in the States. It is hence not wonderful that the progress of such establishments as Kew, the British Museum, South Kensington Museum, &c., should be better known amongst all classes of the people there than they are in the United Kingdom generally, and so I found it."

Under the head of "Interchange of Plants and Seeds," as also under that of "Official Correspondence," a vast deal of information is gathered together on the acclimatisation, extended cultivation, or further development of useful plants. Thus we find the ipecacuanha (*Cephaëlis ipecacuanha*), a native of Brazil, has been distributed from the Calcutta Botanic Garden to Ceylon, Singapore, Burmah, and the Andamans. Dr. King, however, does not take a very hopeful view of its ultimate success in India, partly on account of its peculiarly slow growth, which tends to prevent its cultivation being taken up with spirit by European planters, and partly on account of its insignificant appearance, which does not even excite interest among the planters. Sir Joseph suggests it as "worthy of consideration whether the Indian government would not do well to establish a nursery in some part of our Indian possessions, with the tropical climatic conditions necessary for its growth." In connection with this subject, considering the great value of the ipecacuanha in cases of dysentery, it is satisfactory to note that there seems some prospect of its cultivation being attempted in the native states of Perak, where the soil and climate are considered to be well adapted to its requirements. Regarding the prophylactic virtues of *Eucalyptus globulus*—a subject which has been to some extent ventilated in our own columns—the experiences of the Kew authorities do not throw any further light on it. As valuable timber-trees, however, there can be no doubt that many of the species of *Eucalyptus* will prove most valuable. Sir Joseph says:—"The merits of the numerous species of

this genus are beginning to be understood, and there is no doubt that, where the climate is suitable, few timber-trees can compare with them for rapidity of growth and excellence of wood. Popular misconceptions still, however, prevail on the subject, to some extent. Attempts to grow in tropical climates the species of temperate ones such as *Eucalyptus globulus* can only result in disappointment."

Two points of interest are recorded in connection with the botanical origin of Shiraz and Havana tobaccos. Hitherto the former has been stated, even upon the best authorities, to have been furnished by *Nicotiana persica*. It has, however, been proved from plants raised at Kew from seed of the finest Shiraz tobacco procured from Persia, to be merely a form of *Nicotiana tabacum*, the plant so largely cultivated in North America, and from which the bulk of the commercial tobacco is procured. To the same plant *N. tabacum*, var. *macrophyllum*, is attributed the Cuba and Havana kinds, which have always been described as the produce of *N. repanda*, no such species, so far as Dr. Vidal, the director of the Botanical Gardens, Manila, is aware, being found now in Cuba, either wild or cultivated.

An interesting subject is that connected with vegetable poisons, more particularly the arrow poisons. It is, as is stated, a subject "well deserving of investigation, although it has been doubted whether the ingredients employed have any really poisonous qualities." The evidence on these points is conflicting. Some of the plants from which these poisons are obtained have been promised to Kew, so that before long we shall no doubt know something more definite about them.

Altogether the Kew report is, this year, one worthy not only of perusal, but to be retained for future reference.

NOTES

WITHIN a short period Vienna has lost two of her leading scientific celebrities, von Littrow and von Ettingshausen. We regret to add to the list the name of Baron Karl von Rokitansky, the President of the Vienna Academy of Sciences, who died on July 23 at the age of seventy-four. He was born at Königgrätz, in Bohemia, February 19, 1804. After completing his medical studies at the Universities of Prague and Vienna, he became, in 1828, assistant in the Pathological Anatomical Institute at Vienna. In 1834 he accepted the chair of pathological anatomy in the University, fulfilling, in addition, the duties of prosector in the Vienna hospital, and of legal anatomist for the city. In these varied functions an enormous mass of observations was accumulated, which served as a basis for his "Lehrbuch der pathologischen Anatomie," which appeared in five volumes, 1842-1846, and has survived three editions. At this period von Rokitansky commenced a remarkable series of investigations with the microscope, which Johannes Müller, a few years previously, had introduced into physiological research. From the results of these and other lines of investigation, he rapidly won for pathological anatomy an importance which had been hitherto wanting in German schools of medicine, and caused its recognition as the foundation for all research, not only in pathological physiology, but in the whole province of medicine. The old symptomatic system of classification was replaced by a careful discriminating study of the changes brought about in individual organs by the varied forms of disease. The delicate appliances of modern science enabled him to detect a large number of new diseases, which had hitherto been classed with other diseases on account of the apparent similarity in symptoms. To the classical researches of von Rokitansky, probably more than to any other source, modern diagnosis owes its perfection. The impulse given by him was ably seconded by the contemporary medical authorities of Austria, and on the basis of the principles formulated by von Rokitansky, Hebra in dermatology, Engel in general anatomy, Oppolzer in therapeutics, and Dittrich, Schuh, and Skoda in other special departments of medicine have grounded the famous so-called Vienna-Prague school. Von Rokitansky retired from his professorship three years ago, and published at the same time his last work, "Die Defekte der Scheidewände des Herzens." His merits won for him numerous marks of distinction, and for some time past he has presided over the Imperial Academy of Sciences. He leaves behind him a son, Professor of Music at the Vienna Conservatorium.

WE have received, from the Ethnological Museum of Leipzig, a circular, signed by Drs. Magnus and Pechuël-Loesche, of great importance in reference to the much-debated question as to the development of the sense of colour in men. The object of this circular is to obtain data as to what degree uncivilised peoples perceive colours and distinguish them by names, after the manner of civilised nations. The circular contains a series of inquiries in German and English, along with a scale of colours, and a schedule in which to record the replies to the various questions. The instructions are carefully drawn up, and Drs. Magnus and Loesche intend to distribute the circular by thousands; if the instructions are strictly adhered to the result must be of great value. We believe this circular is only the first of a long series which Dr. Pechuël-Loesche is preparing with the intention of enlarging, in a systematic way, our ethnological knowledge, and especially to solve interesting psychological problems regarding uncivilised tribes. The Ethnological Museum of Leipzig has agreed to receive and take care of all the material collected, which will be at the command of any scientific inquirers who may care to make use of it. We need say nothing in support of this enterprise of Drs. Magnus and Loesche; we would simply urge upon all our readers who are in a position to lend a helping hand, either directly or through friends living abroad, to obtain a supply of the circular referred to, by applying to Dr. Pechuël-Loesche, Museum für Völkerkunde, Leipzig, Germany.

IN the year 1851 the Vienna Academy of Sciences offered a prize for determination of the "Crystalline forms of products obtained in chemical laboratories," which proved fruitful, to a remarkable extent, in crystallographic researches of much importance. More recently new problems have come up with reference to crystallisation, partly in consequence of the labours just referred to, and partly because of the new discoveries of chemistry with regard to the structure of chemical molecules. Wishing to promote research in this direction, the Academy offer a prize of 1,000fl. for "Investigation of the crystalline form of chemical substances, with special reference to homologous series and isomeric groups. A determination of the specific gravity is also desired. The carrying out of optical researches on the crystals measured is deferred for measurement by the winner of the prize." The limit of time is December 31, 1879, and the prize will be awarded in 1880. Papers to be sent in with sealed envelopes and mottoes.

PROF. TAIT is, we hear, engaged in developing for fog-signalling purposes a form of apparatus producing intense sounds with great economy of driving power, which he some time ago exhibited at the Royal Society of Edinburgh. His mechanism is, we believe, devised to produce an effect analogous to that of the drum, which is one of the most economic of noise-producing instruments.

THE commission appointed by the French Government to test the rope used by M. Giffard in the construction of his captive balloon have made their experiments. We have already said that the rope is conical, the heaviest end being uppermost, so that, if any breakage should take place, it will not be in the vicinity of the car, but close to the

earth. The resistance of the smaller end has been found equal to 24,000 kilos of traction exerted by hydraulic pressure, and is smaller than anticipated. It had been suggested by Mr. Newall to employ a wire rope of his own make, which would have had a much greater resistance with a smaller weight; but the suggestion was lost, M. Giffard fearing some electric discharge might ignite the gas. The commission has given its authorisation to admit the public, but under the condition that the pressure should be limited to a quarter of the breaking-strain, viz., 8,000 kilos. The ascending-power is generally 5,000 kilos (about 12,000 lbs.). The difference left to bear the pressure of the wind will be about 5,000 lbs. for a balloon whose surface is $4 \times 1,170$ square yards. The breaking of the rope answers to a resistance of 50,000 lbs., or about ten lbs. per square foot of a plane; it can bear very high wind, and need fear only a tempest. Some observations have already been made by M. Tissandier, but in a somewhat rough manner. An anemometer will be constructed in the car, and its readings will be compared with the readings at the steelyard, to which the rope is attached.

ON July 26, the Council of the Paris Observatory held its quarterly meeting under the presidency of M. Dumas. Admiral Mouchez read a memoir on the most urgent reforms required for the better working of the institution. The new director insists upon the necessity of having a watch kept all night irrespective of the state of weather, for observations to be taken with the meridian circle. Such is the practice at the naval observatory of Montsouris, of which Admiral Mouchez continues to be the director. A large augmentation is required in the *personnel*, a supplementary sum of 54,000 fr. having been asked for that purpose. The Chinese ambassador visited the observatory on July 24, when a large mirror was almost instantly silvered by the Foucault process.

THE French *Journal Officiel* has published the names of those appointed by the Minister to act during three years as members of the Central Bureau of Meteorology. M. Hervé Mangon, and Admiral Mouchez have been appointed to represent the Academy of Sciences, M. Vicomte d'Arlot, sub-director of the Oriental and Chinese Department as delegate of the Foreign Office, Dr. Du Mesnil, Physician of the National Asylum of Vincennes, delegate of the Home Office; Commander Perrier, Member of the Bureau des Longitudes, to represent the War Office; M. Vice-Admiral Cloué, Director of the French Survey, representing the Ministry of Marine; M. Leon Lalanne, Engineer of the Ponts-et-Chaussées, representing the Department of Public Works; M. Cyrien Girard, Member of the Chamber of Deputies, representing the Ministry of Agriculture; M. Berthelot, Member of the Institute, representing the Ministry of Public Instruction; with General Farre, President of the Committee of Fortifications, M. Blavier, Telegraphic Engineer of the Government, to represent the French Postal Telegraphic Administration. The appointments of the officials to fill the several departments of the Central Bureau will soon be made public. It was decided that the Meteorological Bureau will leave the observatory at any cost. An hotel will be obtained for its use in the Rue de Grenelle, Saint Germain, in a part of Paris, which although not central, is at least thickly populated.

A COMMISSION, appointed by the U.S. Congress to select a new site for the Naval Observatory at Washington, held its first meeting on July 15. According to the *New York Tribune*, no money has been voted for expenses, and the Commissioners must therefore be in rather an awkward predicament. The old observatory, in which so much excellent work has been done, is in a very dilapidated condition, and we cannot believe that the U.S. Government will be so parsimonious as to allow the Washington Observatory to lose its place as one of the first institutions of the kind in the world.

AMONGST a large number of designs for the Spinoza monument at the Hague, only two were deemed suitable by the Committee; they were furnished by the sculptors, M. Fr. Hexamer, of Paris, and Herr Joseph Tüshaus, of Düsseldorf. The monument will be erected after the design of the former sculptor.

ON June 1 last, the hundredth anniversary of the foundation of the Society of Arts and Sciences at Batavia was celebrated by a large assembly of members and friends. This Society is the first learned European association which was formed upon Asiatic soil.

AT the Jardin d'Acclimatation at Paris, three enormous tortoises have recently arrived from the Seychelles. The largest of the three weighs no less than 187 kilogrammes (nearly 4 cwt.), and measures 1·17 metres in diameter (about 46 inches).

DR F. MOOK, who for some time past has been busily engaged in making excavations in different parts of Egypt, has just returned to Freiburg (Baden), with a large collection of antiquities. There is no doubt that his collection is the most complete in its special direction which has ever been brought to Europe. It contains no less than 340 skulls from the tombs of Thebes, Dendera, Abydos, and the Pyramid fields, all in the most perfect preservation. Besides these there are some eighty animal mummies, a large quantity of flint implements from Nubia and Egypt, vases, amulets, ornaments, &c. The collection is now exhibited in the University buildings at Freiburg.

WE have received from Messrs. Eberstein, of Dresden, a specimen of an interesting "walking-stick for naturalists or tourists." The stick is a perfect *multum in parvo*, and contains quite a museum of scientific instruments. The handle alone contains a compass, a double magnifying glass, or pocket microscope, and a whistle. Below it there is a thermometer on one side of the stick and a sand-glass on the other. The body of the stick is partly hollow, and in its interior holds a small bottle, which is intended to contain chloroform or ether for killing insects. Along the outside of the body there is a half-metre measure, showing decimetres and centimetres. Near the end of the stick a knife-blade may be opened, which serves for cutting off objects which cannot be reached by hand, such as aquatic plants, &c. At the extreme end a screw may hold in turn a spade (for botanists), a hammer (for geologists or mineralogists), a hatchet, or a strong spike, which would be of great use on glaciers. The whole is neatly finished in black polished wood.

THE following is the title of the essay to which the Howard Medal of the Statistical Society will be awarded in November, 1879:—"On the Improvements that have taken place in the Education of Children and Young Persons during the Eighteenth and Nineteenth Centuries." The essays to be sent in on or before June 30, 1879.

NEXT Sunday evening, August 4, from 6 to 8 P.M., is the last Sunday on which the Grosvenor Gallery will be open to the public this season. Tickets may be obtained by forwarding stamped envelope to the Hon. Sec., Sunday Society, 19, Charing Cross, S.W. More than 3,000 persons visited the Gallery on Sunday evening, July 21.

IN a paper in the last number of the *Journal* of the Statistical Society, on "Failures in England and Wales," it is pointed out, by reference to the tables in Prof. B. Stewart's papers in NATURE, vol. xvi. pp. 9, 26, and 45, that there seems to be some relation between the number of failures and sun-spot periods, just as there is between famines and the periodicity of the same solar phenomenon. Indeed, it is easy to see that this phenomenon must have a widespread influence, and in the interest of the most material commercial interests of our own and

other countries, effective measures ought to be taken for its thorough investigation.

THE British Medical Association meets at Bath from August 6 to 9.

NEAR Pombonne (France) the incisor of a mastodon has just been discovered in a sand-pit at a depth of about a metre. It measures 2·95 metres in length, its base is 45 centimetres in diameter, and the whole weighs some 250 kilogrammes. The ivory at the point is particularly well preserved.

THE General Meeting of the German Anthropological Society will take place at Kiel on August 12–14. Prof. Fraas, of Stuttgart, will speak on the drawing-up of a prehistoric map of Germany; Prof. Virchow, of Berlin, on the statistics of the shapes of skulls in Germany; and Prof. Schaaffhausen, of Bonn, on the compilation of a general catalogue of all the anthropological material in Germany.

THE Geologists' Association have arranged for an excursion to the Boulonnais on August 5, and five following days, which, judging from the admirable programme, promises both pleasure and profit to those who join it.

DR. SCHLIEMANN is at Constantinople, and intends resuming his excavations in the Troad if he can obtain from the Porte fifty soldiers as a guard against robbers. From Berlin it is stated that a summary account of the German excavations at Olympia says that the number of marble objects found during the last three winters is 904; of bronzes, 3,734; of terra cottas, 904; of inscriptions, 429; and of coins, 1,270. All the more important ruins have been photographed, and the third volume of the official account is about to appear. An exhibition of all the casts taken will shortly be opened at Berlin.

THE Jardin d'Acclimatation of Paris offers, during the present year, numerous opportunities for ethnological study. The latest arrival is a party of Guachos from the Pampas of South America, consisting of six men, three women, and a child. They are accompanied by a complete collection of the animals of the Argentine Republic, and by seventeen wild horses. The capture of the horses at full gallop with the lasso forms their chief exhibition.

A SECOND edition of Hooker's standard "Student's Flora of the British Islands," has just been published by Macmillan and Co.; several emendations have been introduced.

WE alluded recently to the remarkable record of earthquakes preserved through so many centuries in Japan. Mr. Hattori, of Tokio, has lately described an ingenious seismograph, which was invented by one Choko, 1,750 years ago. It consisted of a cylinder 8 feet in height, ornamented by various characters and designs. The upper part was encircled by a series of eight dragon's heads, in the open mouth of each of which, a copper ball was lightly balanced. The interior of the cylinder was occupied by a system of rods and springs, so delicately joined that the slightest trembling of the earth would serve to push a ball from a dragon's mouth. Immediately below each dragon's head was a frog looking upward, with his mouth likewise wide open, to receive the balls. The sound of the falling ball would call attention to the phenomenon, and the direction of the earthquake would be revealed by the particular ball dropped. This seismograph correctly recorded earthquakes, which were felt strongly at a distance, but were too feeble to be noticed by the senses in the immediate vicinity.

THE African traveller, Hildebrandt, recommends strongly, in the *Korrespondenzblatt der afrik. Gesellschaft*, the use of petroleum for those travelling in the tropics, as a protection against insects. Occasional applications to the face and hands ensured entire freedom from mosquitoes, and the same method sufficed to preserve horses and cattle against the deadly attack of the Dondorobo gadfly, which so often cripples the movements of the explorer. Petroleum, likewise, protected the natural history collections of the traveller from ants, moths, &c.

THE contributors to the *Zeitschrift für wissenschaftliche Zoologie* have just completed the issue of a supplemental volume of 634 pages, following on their thirtieth volume, as a testimonial offering to Carl Theodor von Siebold on the fiftieth anniversary of his doctorate, April 22, 1878. Prof. von Siebold was for long the chief conductor of this most important journal, having now associated with him as active editor Prof. Ehlers. The festival volume is remarkable for the number and eminence of the contributors, and the importance of their contributions. There are more than twenty authors, including Haeckel, R. Leuckart, Ehlers, Oscar Schmidt, von Thering, Forel, Stiela, Weismann, Simroth, F. Leydig, Salensky, Carl Vogt, Möbius, Repiachoff, and L. Graff. Leydig on the Amphipods and Isopods, Möbius on the movements of flying fish through the air, Haeckel on the phylogeny of the Echinoderms, Flögel on the brains of insects, may be mentioned as memoirs of the most valuable kind.

MESSRS. LONGMANS have sent us vol. iv. of "Ure's Dictionary of Arts, Manufactures, and Mines," edited by Mr. Robert Hunt, F.R.S. This volume is supplementary to the preceding three, and it is apparent that an earnest attempt has been made to record all additions, improvements, and new applications of value.

WE have received from Messrs. Maclure and Macdonald the first four parts of a beautifully and faithfully executed series of Portraits of Distinguished Men, among which are the portraits of several men of science—Sir Joseph Hooker, Prof. Owen, Dr. Allen Thomson. The future parts will contain other portraits of men well known in the scientific world. Each portrait is accompanied by a suitable notice, and the work as a whole deserves hearty encouragement.

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus*) from India, presented by Dr. Adcock; a Burrowing Owl (*Speohyto cunicularia*) from America, presented by Dr. Geo. E. P. Nixon; a Green-winged Dove (*Chalcophaps indica*) from India, presented by Capt. Otho N. Shaw; six Common Guillemots (*Uria troile*), British Isles, presented by Sir Hew. Dalrymple, Bart.; a Common Nightingale (*Daulias luscinia*), European, presented by Mr. Gee; five Great Bustards (*Obis tarda*), a European Bearded Vulture (*Gypaëtus barbatus*), a Spanish Imperial Eagle (*Aquila adalberti*), a Bonelli's Eagle (*Nisaëtus fasciatus*), a Booted Eagle (*Nisaetus pennatus*), two Lanner Falcons (*Falco lanarius*) from Southern Spain, a Red and Blue Macaw (*Ara macao*), a Blue and Yellow Macaw (*Ara ararauna*) from South America, deposited; an Orang-outang (*Simia satyrus*) from Borneo, a Coati (*Nasua nasica*) from South America, two American Flying Squirrels (*Sciuropterus volucella*) from North America, received in exchange.

THE MOVEMENTS OF FLYING FISH THROUGH THE AIR

THESE movements form the subject of an interesting paper recently contributed by Prof. Möbius to the *Zeitschrift für wissenschaftliche Zoologie* (Band xxx., suppl., p. 343; see *Naturforscher*, June 8, 1878). From his own observations (made during a voyage to Mauritius, *viâ* Suez, and back by the Seychelles) and the observations of others, he describes the principal features of the phenomenon thus:—

The exocœti dart with great velocity out of the water without regard to the direction of the wind and the course of the waves. They do not, during their flight, make any regular fluttering

movements with their pectoral and ventral fins, but hold them spread out. In the outspread fins there may occur very rapid vibrations.

The hinder part of the body remains somewhat lower than the fore part during flight.

Directly against the wind they commonly fly further than with the wind, or when their course and the direction of the wind form an angle together.

Most exocœti which fly against the wind or with the wind continue during their whole course of flight in the direction in which they come out of the water. Winds coming laterally upon the original course of the exocœti deflect these into their direction.

All exocœti which withdraw from ships fly during their whole course through the air, near the surface of the water.

When with strong winds they fly against the course of the waves, they commonly rise somewhat over each wave; sometimes their tail dips slightly in the top of the wave.

Only those exocœti whose air-course is crossed by a ship rise to considerable heights (at the most about five metres above the surface of the sea).

By day flying fish seldom light on the ship; they mostly do so at night, and never in calm, but only when the wind is blowing. They mostly fall upon ships which lie not higher than two to three metres above water, and when these are sailing on a wind (the wind coming obliquely from beyond) or with half a wind (the wind coming at right angles against the ship), and are sailing rapidly. Flying fish never come on board from the lee side, but always and only from the weather side.

Not uncommonly when their tail has dipped in the water they describe in the horizontal part of their course, a bow to the right or to the left side.

During wind and a rough sea they appear above the water more frequently than in calm weather.

Before ships, which come upon them in swimming, the exocœti escape into the air, just as they do before fishes of prey and cetacea.

Many authors have affirmed, in explaining the flying of fish, that the pectoral fins operate like the wings of birds, bats, and of insects. Prof. Möbius, however, shows that both the anatomical structures of the pectoral fins and their muscles, and the physiological relations of the position and size of the fins to the volume and weight of the whole body, are against flight-like movements of the pectoral fins.

The movements occasionally observed in these organs during flight are merely a vibration.

The true cause of these movements of fishes through the air are the spring-movements which they impart to their body by means of their very strong side muscles, just as other fish propel themselves powerfully through water. They spring out of the water with great velocity, because the air presents less resistance than the water, and when after some time, they fall back into the water, their outspread fins act like a parachute.

It is easy to understand how the action of the wind combines favourably or otherwise with their flight. By day the direction of their spring is so chosen that the disturbing ship is avoided. By night this orientation by the sense of sight is wanting, and the animals fall into the ship. As any air in strong motion, when it impinges against obstacles (a ship's side or waves), rises, it raises also the fish, so that this flies over the wave, or may come on board the ship. In short, as Prof. Möbius proves in detail, all the phenomena observed may be fully explained by the combined action of the oblique projection forwards and the wind. It may further be mentioned that the flying fish has a peculiar arrangement of the mouth, so that in this a portion of water may be carried during flight for the process of respiration.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

The Kingdom of Portugal has for its 4,700,000 inhabitants but a single university—that of Coimbra, which was originally founded at Lisbon in 1290. The university has a corps of instructors numbering 70, is attended by 1,100 students, possesses a library of 42,000 volumes, and is equipped with astronomical and meteorological observatories, as well as natural history collections. Advanced education is likewise provided for by polytechnics, medical academies, and industrial institutes in Lisbon and Oporto, and an agricultural school. The elementary schools of the land number 2,450, and parents lose their political rights if their children cannot read and write at the age of 15.

The University of Strasburg is attended at present by the largest number of students recorded since its establishment, viz., 710, consisting of 45 in theology, 195 in law, 150 in medicine, 177 in philosophy, and 143 in science.

The new regulations for medical study in France require a term of four years, five examinations, including one in physics, chemistry, and natural history, practical work in the laboratories and anatomical theatre, and two years visiting of the hospitals. The sum requisite for this course of study is 1,360 francs—520 for lectures, and the remainder for examination fees, thesis, and diploma.

An examination will begin at Merton College, Oxford, on Tuesday, October 15, for the purpose of electing to a Physical Science Postmastership of the annual value of 80*l.*, and tenable for five years from election. After two years of residence the College will raise, by a sum not exceeding 20*l.* per annum, the postmasterships of such postmasters as shall be recommended by the tutors for their character, industry, and ability. Candidates, if members of the University, must not have exceeded six terms of University standing. Information may be obtained from the tutor in physical science.

Mr. Samuel Sharpe has promised to give 5,000*l.* towards the building of the north wing of University College, London, so soon as the Council are prepared to begin the work. It is expected that this liberal donation, together with others which have been received, will enable the building to be very shortly commenced. A sum of 50,000*l.* in all will, however, be required to complete the extensions which are immediately contemplated.

SOCIETIES AND ACADEMIES

London

Anthropological Institute, June 25.—Mr. John Evans, D.C.L., F.R.S., president, in the chair.—Dr. Paul Topinard, of Paris, was elected an Honorary Member, and the election of the following gentlemen as Ordinary Members was announced:—The Rev. H. W. Watkins, Warden of St. Augustine's College, Canterbury; Hy. Wm. Jackson, M.R.C.S., F.R.A.S., F.G.S., of Lewisham, and Dr. Dunkley, of New Zealand.—A paper was read on the ethnology of the islands of the Pacific, by the Rev. S. J. Whitmee. This paper was chiefly intended to explain an ethnographic chart of the Pacific, coloured according to the author's own observations, and which, in the main, followed the divisions of races in previous charts. In speaking of the people, he said the Melanesians, or black race, might be regarded as the aboriginal people, and that they had affinities, more or less remote, with the blacks found in the various parts of the southern hemisphere. Probably these Melanesians once extended further across the Pacific than they now do. The brown Malayo-Polynesian race had, doubtless, entered Polynesia from the west. The difficulties of such a migration were not insuperable. An example was given of a comparatively recent arrival of a vessel thought to be Chinese or Japanese, at Fotuna, or Home Island, containing forty people. There is a third people in Polynesia differing considerably from both of the others. These are the Micronesians. They probably are primarily from the Philippines, or some other portion of the Indian Archipelago, but are mixed with Melanesian and Malayo-Polynesian blood. There is also reason to believe they have had an admixture of Chinese or Japanese blood derived from the occupants of junks which have been driven by adverse winds to this region.—Mr. Worthington G. Smith read a paper descriptive of palæolithic implements from the gravels of N.E. London, and a paper was communicated by Mr. G. M. Atkinson on a new method of finding the cephalic index.

Entomological Society, July 3.—H. W. Bates, F.L.S., F.Z.S., president, in the chair.—Mr. Basil G. Nevinson was elected an Ordinary Member and Mr. John A. Finzi a Subscriber.—M. Pascoe exhibited a number of insects he had collected during a recent tour through Algeria and the south of Spain; with these there was a remarkable myriopod having the cylindrical body of the Julidæ, but with only one pair of legs to each somite.—Mr. Boyd drew attention to the food plant of *Eluchista cerusella*. This insect had always been considered to feed on the leaves of *Arundo phragmites*, which Mr. Boyd doubted, as he had lately found the larva feeding on *Phalaris arundinacea*,

a grass which somewhat resembled the other plant before the flowers appear.—Mr. Distant exhibited some specimens of the homopteron *Ricania australis*, Walk., which had been sent him for identification through Dr. Sharp, from Mr. Lawson, of Auckland, New Zealand, where the species had been observed last year on the dahlia for the first time. These New Zealand forms were, however, much darker in colour than Australian specimens, and hence had probably been introduced for some time. Mr. Jenner Weir exhibited two specimens of *Leucania turca* with several pollinia of *Habenaria bifolia* attached to the trunk of each, and which was only observed in these two instances out of fifty specimens examined. Mr. Weir also exhibited an interesting variety of *Hipparchia hyperanthus*.—Prof. Westwood remarked on a recent note in NATURE, vol. xviii. p. 226, referring to observations made by Dr. A. S. Packard on the manner in which lepidoptera escape from their cocoons, and stated that similar observations had been previously made and recorded by Capt. Hutton (*Trans.* Ent. Soc., 1st. ser. vol. v. p. 85). Prof. Westwood also stated that he had recently heard of injuries done to potato crops by *Cetonia aurata*, which had been found stripping the leaves, and a lepidopterous larva (probably a species of *Botys*), which bored into the stem.—Mr. Dunning read a note on spiders resembling flowers.—The Secretary read a note from Mr. J. Haselden relating to the habits of the honey bee (*Apis fasciata?*) in Egypt.—Mr. Waterhouse communicated a paper on new coleoptera from Australia and Tasmania in the collection of the British Museum.

CAMBRIDGE

Philosophical Society, May 20.—A communication was made by the Rev. E. Hill, on some points connected with the influence of geological changes on the earth's axis of rotation.—The author proved by elementary methods the following results recently obtained by Mr. G. H. Darwin :—(1) That small deformations of the earth cannot alter the position in space of the earth's axis of rotation. For if external forces be neglected this follows immediately from the conservation of angular moments. If we introduce the attractions of the sun and moon, the investigation of precession and nutation will in general still apply to the deformed earth, and the mean obliquity be unchanged. 2. That these deformations cannot sensibly separate the axis of figure from that of rotation. It was shown that as soon as a separation began, the rotation-pole would appear to trace out on the surface a cyclone with its base in the direction along which the figure-pole might be shifting; that the two would coincide about every 300 days, and the greatest divergence thus be infinitesimal. 3. That should the earth yield to strain, these poles would describe a spiral on the surface. This was only shown in a single case. 4. Expansion and contraction will be less effective in shifting the principal axes than transference of surface-matter. For expansion and contraction involve transference of matter from within outwards, or *vice versâ*, and the effect of increase of matter at one point of a radius would be more or less counterbalanced by its subtraction from another point. But transference of matter on the surface may be so arranged that the gain at one point is reinforced by the loss at the other.

MANCHESTER

Literary and Philosophical Society, December 4, 1877.—Transit of the shadow of Titan across the disc of Saturn, November 23, 1877, by Joseph Baxendell, F.R.A.S.

February 11, 1878.—Mr. Binney, F.R.S., sent a marine alga from the Isle of Man for identification. It was not in fruit, but was undoubtedly an unusually narrow fronded form of *Chondrus crispus* (Lamx.).—Mr. C. Bailey, in the absence of Mr. Hurst, read a paper by the latter on the best method of collecting and preserving plants for herbarium purposes, when gathered in tropical or subtropical countries.—Mr. J. Boyd exhibited slides of *Spongilla fluviatilis*, the fresh-water sponge, showing spicules.

February 25.—Results and deductions of rain-gauge observations made at Eccles, near Manchester, during the year 1877, by Thomas Mackereth, F.R.A.S., F.M.S.

March 5.—On the decomposition of ultramarine by carbonic acid, by Mr. S. Sugiura (Student in the Chemical Laboratory of the Owens College). Communicated by Prof. Roscoe, F.R.S.—On siliceous fossilisation, by J. B. Hannay, F.R.S.E., Assistant Lecturer on Chemistry in the Owens College. Communicated by Prof. Roscoe, F.R.S.

March 11.—On bryozoa, by Arthur Wm. Waters, F.G.S.

March 19.—On a remarkable flash of lightning, by B. St. J. B. Joule.—On a barometer, by Dr. J. P. Joule, F.R.S.—A comparison of the standard barometer of the Owens College Physical Laboratory with the working barometer, by Mr. Morisabro Hiraoka, Student of Owens College. Communicated by Prof. B. Stewart, LL.D., F.R.S.—On a new calorimeter, by J. B. Hannay, F.R.S.E., Assistant Lecturer on Chemistry, Owens College.

VIENNA

Imperial Academy of Sciences, March 14.—On processes of degeneration and regeneration in normal peripheric nerves, by Herr Mayer.—Embryology of ferns, by Herr Leitgeb.—New experiments in proof of Döppler's theory of tone and colour variation through motion, by Dr. Mach.—Researches on the origins and the functions of the accelerating nerves, by Dr. Stricker.—On a fluorescein-carbon acid, by Dr. Schreder.—On phenomena in the circulatory apparatus after temporary closure of the aorta (a contribution to physiology of the spinal cord), by Dr. Mayer.—On the salivary glands of *Eledone moschata*, by Dr. Dietl.—On a new geological inclosure in the region of the Carlsbad springs, by Prof. Hochstetter.—On the magnetic declination and inclination at Vienna, by Herr Liznar.—The daily and yearly course of temperature at Port Saïd and Suez, by Herr Kostlivz.

March 21.—On peculiar openings in the upper surface flower leaves of *Francisea macrantha*, Pohl, by Dr. Waldner.—On the electromotive force of metals in aqueous solutions of their sulphates, nitrates, and chlorides, by Dr. Streintz.—On the diffusion of carbonic acid through water and alcohol, by Dr. Stefan.

April 4.—The following, among other papers, were read:—On determination of electric resistance by the electrostatic method, by Herren Gruss and Biermann.—On the heat capacity of mixtures of methylic alcohol and water, by Herr Lecher.—Main features of the actinic theory of heat, by Herr Reschl.—The basaltic lava of the Eifel, by Herr Hussak.—On the organisation of the brain of invertebrates, by Dr. Dietl.—On the arrangement of the more recent tertiary formations of Upper Italy, by Dr. Fuchs.—On Canides from the diluvium, by Dr. Woldrich.

April 11.—New and rare fish of the Vienna museum, by Dr. Steindachner.—Two problems of the dynamical theory of gases, by Lieut. Schlemüller.—The products of the volcano Monte Ferru, by Prof. Doelter.—The geological formation of Attica, Bœotia, Locris, and Parnassus, by Dr. Bittner.—On great subterranean watercourses and reservoirs, and the purity and transparency of certain lakes, by Dr. Boué.—On peculiar properties of some astronomical instruments, by Herr Sterneck.

May 9.—The dolomite ridges of Southern Tyrol and Venetia, by Dr. v. Mojsisovics.—The reptiles and fishes of the Bohemian chalk formation, by Prof. Fric.—On the results of the meteorology of the present, by Herr Hann.—Fish fauna of the Magdalene stream, by Dr. Steindachner.—Nostocolonies in the thallus of the Anthoceroteæ, by Prof. Leitgeb.—On continuous acoustic rotations and their relation to the principle of surfaces, by Herr Haberditzl.—Comparative anatomy of the seeds of *Vicia* and *Ervum*, by Dr. Beck.—Experimental pathology of œdema of the lungs, by Dr. Mayer.—On the electrolysis of water, by Dr. Exner.—On the relative volumes of atoms, by Herr Wächter.—Development of Chætopoda, by Prof. Stossich.—Chemical composition of diastase and grape jelly, by Prof. Zulkowsky.—Interpolar electrotonus, by Dr. Fleischl.—On the internal friction of glycerine, by Herr Schöttner.

May 16.—On the colours which follow each other in Newton's ring system, by Prof. Rollett.—On azophenols, by Prof. Weselsky and Dr. Benedikt.—On the existence of man at the time of the loess formation, by Count Wurmbrand.—On the apparently secular variations of dry land, by Prof. Suess.

May 23.—On the course of spark-waves in the plane and in space, by Prof. Mach.—On the path of the Comet II. of 1873, by Herr Becka.—Influence of pressure and temperature on the spectra of vapours and gases, by Herr Ciamician.—Theory and application of electro-magnetic rotations, by Dr. Margules.—The laws of the individuality of planets of our solar system; attempt to found a general theory, by Herr Lehmann.—Stones

from the peninsula Chalcidice, by Herr Becke. On Berberin, by Dr. Weidel.

June 6.—The following, among other papers, were read:—Contributions to a knowledge of the colour-change of Cephalopoda, by Dr. Klemensiewicz.—On some problems of the mechanical theory of heat (continued), by Prof. Boltzmann.—On the cold-mixture of chloride of calcium and snow, by Dr. Hammerl.—On the gases arising from action of barium-oxide hydrate on albuminous substances, by Dr. Liebermann.—On the mica group (second part), by Herr Tschermak.

June 21.—The protoplasm of the pea (second part), by Prof. Tangl.—On development of hydrogen in the liver, and a method of production of butyric acid of fermentation, by Prof. Pribram.—On the specific viscosity of liquids, by Profs. Pribram and Handl.—Relations between electromotive force and chemical heat-tone, by Prof. Sekulie.—On the best method of showing details of the ethnography of a country with adequate accuracy and completeness in maps, by Prof. Boué.—On motion of electricity in space and Nobili's rings, by Prof. Ditscheiner.

July 4.—Map of the mountains of the moon, from personal observations in the years 1840–1874, by Dr. Schmidt, of Athens Observatory.—Fourth report from the Adria Commission, giving results of meteorological observations for 1871–73, and maritime observations for 1873.—Yearly periods of the insect fauna of Austria-Hungary, by Herr Fritsch.—Determination of the orbit of Comet V., 1874, by Dr. Gruss.—On the molecular size of indigo, by Prof. Lieben.—On heliotropic phenomena in the plant kingdom, by Prof. Wiesner.—On the friction of vapours, by Dr. Pulnj.

Rome

R. Accademia dei Lincei, May 5.—The following, among other papers, were read:—On fossil bones in the environs of Rome, by Sig. Ponzi.—On personal errors in observation of the duration of meridian passages of the solar diameter, by Sig. Respighi.—Catalogue of the mean declination of stars of the first to the sixth magnitudes, comprised between the parallels 20° and 64° N. lat. (first part), by the same.—Objections to the induction of Messrs. Humphrey and Abbot, and representation by means of a parabolic curve of the subaqueous velocity, by Sig. Fambri.—On the minute structure of the skin of reptiles, by Sig. Todaro.—Histological researches on the pigmental epithelium of the retina, by Dr. Angelucci.—On the serpentine of Verrayes in the Valle d'Aosta, by Sig. Cossa.—On the serpentine formation of the Pavian Apennines; report on memoir, by Sig. Taramelli.—Theory of the boraciferous soffioni of Tuscany, by Sig. Bechi.—Astronomical and physical observations on the axis of rotation and on the topography of the planet Mars, made at the Royal Observatory of Brera, in Milan, with the equatorial of Merx during the opposition of 1877, by Sig. Schiaparelli.

Paris

Academy of Sciences, July 22.—M. Fizeau in the chair.—The following among other papers were read:—On the theory of fermentation, by M. Pasteur. He takes objection to the unauthorised posthumous publication by M. Berthelot of some laboratory notes of Claude Bernard, written in October last, and which seem to be opposed to M. Pasteur's views. The notes were those of experiments made in order to test to the utmost those views, not a manifesto against them. M. Berthelot replied.—On the electro-chemical deposit of cobalt and nickel, by M. Becquerel. He points out the priority of his father's and his own experiments on the subject in 1862.—On the variation of the intensity of currents transmitted through mediocre contacts according to the pressure exerted on them, by M. Du Moncel. He has made various observations on this subject since 1856, and in 1875 noted in metallic filings, &c., properties on which Prof. Hughes' thermoscope microphone is based.—Velocity of propagation of excitations in the motor nerves of muscles of animal life in mammalian animals, by M. Chauveau. The average velocity in frogs was first measured and found about twenty-one metres per second. In the pneumogastric nerve of solipedes great differences were observed both in different parts of the nerve and in different animals. In one ass the velocity in the recurrent branch of the pneumogastric was 51 m., in the pneumogastric 68 m., and in the intermediate section 66·5 m. *The activity of conduction decreases from the origin to the termination of nerves.* In *post-mortem* experiments this law is reversed. If the pneumogastric is cut the conduction is retarded somewhat without reaching the figure for the terminal portion of the recurrent nerve. Operating on the middle portion of nerves, the velocity is about the same in animals placed in the same physiological conditions. It is about 65 m. per second, and may rise to 75 m. in strong animals of high breed, or go below 40 m. in common weak animals.—Currents observed in the Suez Canal and consequences resulting from them, by M. de Lesseps. Lake Timsah and the Bitter Lakes act as regulators. The prevalent north and north-west winds from May to October raise the mean level of water at Port Said and depress it at Suez; hence in summer a current, interrupted by the tides, from the Mediterranean to the Red Sea, and finally driving a good deal of water southwards. In winter the reverse occurs. It is estimated that 400,000,000 cubic metres of water are thus annually driven to and fro. This, with the tides, tends to annihilate the effects of evaporation, and aid the dissolution of the salt banks of the Bitter Lakes.—Note on a new earth of the cerium group, and remarks on a method of analysis of columbates, by Mr. Lawrence Smith (sealed packet deposited September 22, 1877).—On mosandrum, a new element, by the same. The new earth was obtained from samarskite; and he established that it differed from that of the yttria group, from oxide of cerium, from lanthanum, and from didymium. M. Soret has, with the spectroscope, confirmed the existence of the metal constituting the base of this new earth.—Discovery of the periodic comet Tempel at Florence, by M. Tempel.—On an apparatus for demonstrating simultaneously the law of recoil of a gun and the law of motion of a projectile, by M. Sebert. The instrument is called a velocimeter.—On the tension of vapour and the freezing point of saline solutions, by M. Raoult. With regard to power of diminishing the tension of vapour, or retarding the freezing point, the different anhydrous salts rank in nearly the same order. The power of producing the one or the other effect is generally greater the smaller the atomic weight.—On the presence of lead in sub-nitrate of bismuth, by MM. Chapuis and Linossier. A method of detection is described.—On a new hexavalent non-saturated hydrocarbon diallylene, C_6H_8, by M. Henry.—On the presence of lithium in the earths and thermal waters of the Solfatara of Pozzuoli, by M. Luca. It is there found in very small proportion in the state of sulphate.—On the peripheric temperature in febrile maladies, by M. Couty. In febrile affections developed normally the temperature increases in the peripheric parts more than in the central, and there is equalisation, or a tendency to this, in all parts of the body.—Relation between manifestations of ozone and turning movements of the atmosphere; observations in 1877, by M. Gully. The coloration of the paper seems to be always greatest to the north of a centre of depression.

CONTENTS

THURSDAY, AUGUST 8, 1878

THE JOURNAL OF PHYSIOLOGY

Journal of Physiology. Edited, with the co-operation in England of Prof. A. Gamgee, F.R.S., of Manchester, Prof. W. Rutherford, F.R.S., of Edinburgh, Prof. J. Burdon-Sanderson, F.R.S., of London; and in America of Prof. H. P. Bowditch, of Boston, Prof. H. M. Martin, of Baltimore, and Prof. H. C. Wood, of Philadelphia, by Michael Foster, M.D., F.R.S. (London: Macmillan and Co.)

THERE is perhaps no science which is making more rapid advances than that of physiology, and which is at the same time so interesting to general readers, as well as to those engaged in its special prosecution. A knowledge of the processes of life has such a close relation to individual health and happiness that it ought to be more or less taught to every child at school, and all thinking men must note its advances with interest. So swift is the progress of physiological science, that it has necessitated for this journal a mode of publication, now becoming common in Germany, but of which this is perhaps the first example in this country. Instead of appearing at regular intervals, the *Journal of Physiology* is published in numbers, which are issued at periods varying from two to three months, according to the supply of material sent in to the editors. From four to six numbers will form a volume of about 500 pages. The advantage of this mode of publication is that it prevents a discovery made by one man from being forestalled by another whose observations, although really made later in point of time, might sometimes obtain priority under the ordinary method of publication.

The title-page of the *Journal* shows that it is to some extent an international work, three American co-operating with three English professors, under the able editorship of Dr. Michael Foster. The first numbers contain contributions from the Continent of Europe as well as from Great Britain and America, one of the most interesting articles in them being contributed by a German, Prof. Kühne, of Heidelberg. The range of subjects is very wide, and includes papers on almost every function of the body—innervation, motion, circulation, respiration, and secretion. Some time ago an account was given in NATURE of Kühne's interesting discoveries regarding visual purple, that pigment in the eye which is so susceptible to the action of light. In his present paper he takes up the other pigments of the retina, which are either not affected at all, or only to a slight extent, by exposure to light. He has succeeded in discovering and isolating from a bird's retina no less than three distinct pigments of great stability, and he gives in one paper the mode of preparation, properties, and spectroscopic appearances of these substances. In the same paper he simply mentions the black pigment of the retina, which he regards as exceedingly stable, and little altered by light; but while the number of the *Journal* in which his paper is contained was still passing through the press he made the discovery that this pigment does not resist the action of light so perfectly as he at first supposed, and is slowly altered by exposure. This leads him to remark that "if one considers the extremely widespread occurrence in the animal kingdom of the black pigment of the eye and other similarly stable pigments, it is scarcely possible to repress the idea that these, in addition to visual purple, also represent visual excitants, or so-called visual substances, and are intended to be decomposed by light during life, and to yield those substances which stimulate chemically the terminal apparatus of the visual organ." He also calls attention to the remarkable circumstance that the pigments of a bird's retina he has discovered are so mixed with oil globules that the colours in the cones of the retina represent exactly half the spectral colours, viz., from red to yellowish green, so that with their complementary colours they yield all the colours of the spectrum. He also observed that the three pigments are most readily decomposed by blue light, less by green, and not at all by red. Comment is unnecessary on the importance of this paper in reference to vision.

In a preliminary note Mr. Gaskell contributes some interesting observations on the vaso-motor nerves of striated muscles. He had previously found that irritation of the motor nerve of a muscle dilated its vessels, and increased the flow of blood through it, at the same time that contraction was produced so that fresh supplies of nutriment and oxygen were supplied to the muscle by the blood at the same moment that it was stimulated to work. He has now shown that the same phenomena may be produced reflexly by irritating a sensory nerve, and that the dilatation of the vessels will occur, and the blood will flow more freely through the muscle even when it is prevented from moving by paralysing the motor nerves with curare. On then irritating a sensory nerve, the current of blood is increased as usual in the paralysed muscle, which would have contracted under ordinary circumstances, and thus proof is afforded that the vaso-dilating nerves are distinct from the motor nerves of the muscle.

Mr. Priestley gives a full account of the literature regarding the pulsations of the lymph-hearts in the frog, and he details a number of experiments which demonstrate several new facts, as well as confirm the observations of other physiologists.

In a joint paper, Dr. Gamgee and Mr. Priestley criticise Tarchanoff's statement that each vagus nerve can set in action the whole inhibitory apparatus contained in the heart, and that when this apparatus, whose function is to lessen or stop the cardiac beats, has been exhausted by irritation of one vagus no stimulation of the other can stop the cardiac pulsations. Their own experiments show that even when one vagus has been exhausted, irritation of the other will still stop the heart, and even when both are exhausted the inhibitory apparatus is still active, so that the pulsations of the heart may even then be arrested by galvanism applied to the venous sinus. They therefore conclude that the inhibitory apparatus in the heart is much less easily exhausted by stimulation than the vagi, and that it may still retain its power over the heart although both vagi are so exhausted that they will no longer convey to it a stimulus applied to them.

The question as to whether the apex of the frog's heart contains within itself ganglia which will keep up its rhythmical motion has lately been the subject of lively debate, but Dr. Bowditch brings forward a number of

experiments which seem to point strongly towards a negative answer.

An interesting paper on the respiration of the frog is contributed by Prof. Martin, whose observations strongly suggest a close relationship between the nervous centre which regulates respiration and that which regulates general reflex action, even if the two should not be identical. He discusses the question whether there be two independent, though closely related, nervous centres, one for inspiration and the other for expiration, or whether, as supposed by Budge, there is a single centre from which the muscles of inspiration and those of expiration may receive their innervation according to circumstances. Dr. Martin shows that this latter hypothesis does not hold good for the frog, and that in it there are really two distinct centres, one for inspiration, and one for expiration, each having its own stimulus, and generating its own nervous impulse, which can travel in them only to its own set of muscles quite independently of the resistance opposed to discharge from the other centre.

Those who are interested in the electro-motive properties of muscle will find in this journal an admirable report on this subject by Prof. Burdon Sanderson, in which he gives an account of Hermann's recent work in this department of animal electricity, along with such information both regarding modes of investigation and experimental results as greatly facilitate comprehension of the subject.

A most laborious and fatiguing series of experiments has been made by Mr. North on the effects of starvation with and without severe labour, and on the elimination of urea from the body. These experiments were made upon himself, and, in addition to the personal discomfort produced by a complete abstinence from food, he voluntarily underwent severe exercise upon the treadmill, for the purpose of ascertaining exactly the effect of labour upon the excretion of urea. Flint had found that in the case of Weston, the pedestrian, the excretion of urea was considerably increased during a long walk, and Mr. North's observations go to show that severe exercise does increase the elimination of urea, but the increase is very small, both when the person is fed upon ordinary diet, and when nitrogenous food is entirely withheld. The quantity of urea passed, however, depends largely on the condition of the body at the time, varying according to the greater or smaller reserve of nitrogenous material contained in it, and he thinks that Weston, before entering upon his walk, had accumulated a large reserve, from which the urea he excreted was derived.

The paralysis produced by potash salts when injected into the circulation, is usually ascribed to a special action upon the muscles and heart. Dr. Ringer and Mr. Murrell, however, from a number of experiments on the subject, have come to the conclusion that potash has no special affinity for muscle, but is a protoplasmic poison, having an equal affinity for all protoplasm, and destroying the tissues in the order of their vital endowments.

Mr. Langley has made a number of observations upon the salivary glands, and finds that Nussbaum's supposition that the disappearance of the black colouration produced by osmic acid from the sub-maxillary (?) gland after treatment with glycerine is not due to the removal of ferment from the gland, but to some other cause, and that furthermore an amylolytic ferment does not exist at all in the sub-maxillary gland of the rabbit. He finds that there is a marked difference between the cat and the dog in regard to the salivary secretion, the sympathetic secreting nerves having a different connection with the gland cells in the two animals, a difference which favours the paralysing action of atropia in the cat.

The secretion of sweat is now known to be, like that of saliva, directly under the control of the nervous system, and to be excited by secreting nerves, independently of alterations in the vessels which supply secreting glands. Dr. Ott and Mr. Field show that the nerve centres in connection with the sweat glands can be stimulated by the poison muscarine, and that a greater amount of carbonic acid than usual in the circulating blood will also excite functional activity, a fact which would tend to explain the greater tendency to sweat which people observe when they are shut up in a close room, a tendency which appears to be greater than can be readily accounted for by the warmth of the room alone.

These brief observations will give some idea of the variety of physiological subjects discussed in the *Journal of Physiology*, and we heartily congratulate the able editor and his co-operators on the importance and interest of the results set before us in the numbers which have already appeared. We have no doubt that in such competent hands this journal will continue to maintain its high character, and, while absolutely indispensable to all who desire to follow the progress of physiology, it will, we think, do much to diffuse a knowledge of that science amongst general readers.

A UNIVERSAL GEOGRAPHY

Stanford's Compendium of Geography and Travel, based on Hellwald's "Die Erde und ihre Völker." Africa: Edited and extended by Keith Johnston. *Central and South America:* Edited and extended by H. W. Bates. With Ethnological Appendices by A. H. Keane, B.A. Maps and Illustrations. (London: Stanford, 1878.)

HELLWALD'S "Die Erde und ihre Völker" is well known in Germany, and has achieved a great popularity. We doubt, however, if a simple translation of Hellwald's work would have been either fair or wise; for though it is written more brilliantly than German works usually are, and although Hellwald himself is a competent geographer, it has several drawbacks which we should have regarded as serious defects had they been permitted to stand in this English edition. For one thing, Hellwald is a violent Anglophobist, and he takes every opportunity of depreciating English travellers or ignoring them altogether. We therefore think it wise in the publisher of the English edition to take the German work simply as a basis on which to found an English work that shall fairly represent the present state of geographical knowledge. The method adopted by the publisher appears to us well adapted to attain the end in view. He has succeeded in obtaining the services of geographers having a special knowledge of the various divisions of the earth of which the several sections of the work treat. These editors, taking the translation of Hellwald as their raw material, go over it, correcting and extending as far as they deem necessary in order to

produce a work which comes up to their standard. Thus Mr. Keith Johnston has dealt with Africa, and Mr. Bates with Central and South America; of the future volumes, Europe will be edited by Prof. Ramsay, North America by Dr. Hayden, the chief of the U. S. Geological Survey, Asia by Col. Yule, and Australasia by Mr. A. R. Wallace. It must be admitted that no more competent men could be found for the parts allotted to them, and judging from the two volumes before us, the "Compendium of Geography and Travel" ought to take its place as a standard authority on geographical knowledge and geographical exploration.

The volume on Africa by Mr. Keith Johnston, who himself will shortly lead an expedition to that much-explored continent, contains a complete account of our knowledge of the "dark continent," up to the date of publication, including the recent discoveries of Mr. Stanley. After a general introduction, each of the principal regions of the continent, from the region of the Atlas southwards, is treated separately, in all its aspects —physical, geological, topographical, ethnological, and biological. It is evident that Mr. Johnston has added largely to the German original; indeed, his volume is two or three times the size of the section of Hellwald's work devoted to Africa. The result is a work which gives a full and satisfactory summary of our present knowledge of perhaps the most interesting continent of the globe. It would, however, be a mistake to imagine that the work is a dry geographical treatise; it reads more like a well-written narrative of travel, and besides its value to all interested in geography as a standard work of reference, it will be found genuinely interesting reading. Mr. Johnston's Notes on the distribution of rain in Africa, illustrated by a series of fourteen rain-charts, are of distinct scientific value. Mr. Keane's Appendix on the African Races is evidently the result of long and conscientious research; and while he possibly makes too much of language *per se* as a test of race, he is evidently master of his subject, and has gathered together in a clear and well-arranged form a mass of information of great ethnological value.

To many, perhaps, the second volume, on Central and South America, edited and to a considerable extent re-cast by Mr. Bates, will contain more of novelty than the first, treating, as it does, of a region less familiar to the public than Africa. Under the title of Central America the second volume includes not only the smaller states of the isthmus—Guatemala, Honduras, San Salvador, Nicaragua, Costa Rica, and British Honduras—but also Mexico proper, the whole forming a region probably upheaved by volcanic agency, and which seems to taper away gradually from north to south. The area of this large district of country exceeds more than five times that of Spain, and would seem to be sufficiently distinct both in a geographical and geological point of view from those broad continental expanses known as North and South America. The highlands of this district form a series of wonderful lofty table-lands, intersected by detached hilly portions and flanked by commanding volcanic peaks. In some places these table-lands rise in terraces one over the other. In others these will be suddenly interrupted by deep intervening valleys of very various forms, sometimes mere chinks, at other times fissures of variable breadth and upwards of a thousand feet in depth between whose steep rocky walls flow little streamlets. The great mountain-chains culminate in such giant volcanic peaks as Popocatepetl, which is nearly 18,000 feet in height.

In addition to the chapters describing the physical and natural features of this area, and a brief account of its former wondrous greatness, there are chapters on the present inhabitants, and copious information is given as to each of the States. Especially would we note the chapters relating to the population and government of Mexico.

The second division of Mr. Bates's volume is devoted to the West Indian Islands. This large group of islands lying east of Central and north of South America, includes Cuba, Jamaica, Hayti, and the Lesser Antilles. The condensation of this part is carried too far. These islands awaken many memories of the past, not, indeed, of a prehistoric past, like those that cling round Mexico, but as it were of a modern past, with which some of ou own island glory is connected, and it would have been well had the editor not only edited, but extended, from the English point of view, Hellwald's notices of Jamaica, Cuba, and Hayti. In an appendix it is true there is a most useful tabulated survey of the principal islands in this group, which gives details of their population, a list of their chief towns, and a short account of the products and industries of each, but what we would have liked would have been to have had all this incorporated in the text, with a short account of the past greatness if any of each of the larger islands.

The third division treats of South America, a well-defined continent, over some portions of which our editor has often wandered, a continent, the greatest in the world for some of its natural wonders, a continent conspicuous for its mighty mountain ranges, for the peculiar way in which these run, which fact in combination with their great height and their vast woody slopes, accounts for their giving birth to so many gushing streamlets which, in their turn uniting, form so many mighty rivers, by which the future greatness of this part of the world will be achieved. The carefully edited chapters of this section read—though not exaggerated in tone—like so many pages from some tale of fairyland. Passes over mountains upon the snow—just on the very line of eternal whiteness with bright flowers and brighter humming-birds, views from these lofty eminences that no words can describe, views of nature in its vastness and its greatness that seem to pain the human soul because it has to confess its inability to take them wholly in. Then the vast steppes or llanos, then those rivers, such as the Amazon and her tributaries, and lastly the volcanoes. Amid all this nature the great towns and the varied peoples of South America are, however, not overlooked, and there are some good woodcuts illustrating the chief features of both scattered through this portion of the volume.

The chapters also on the natural products and resources of the various tribes and people are most interesting, and the statistics seem to prove that the leaven of civilisation is at last beginning to work in the huge human mass.

The chapter on the ethnography and philology of the American continent, by Mr. Keane, covers 100 pages, and seems all but exhaustive; it is accompanied by several maps, and, as in the case of Africa, by a long list in

alphabetical order of all the known American tribes and their languages. Each volume has a good useful index, a most important item in a work of this nature.

The abundant equipment of maps adds greatly to the value of the volumes, as the numerous illustrations do to their interest.

OUR BOOK SHELF

Geometry in Modern Life, being the Substance of Two Lectures on Useful Geometry, given before the Literary Society at Eton. By J. Scott Russell, F.R.S. (Eton: Williams and Son, 1878.)

IN a recent number (NATURE, vol. xviii. p. 263) we took occasion to suggest that the usefulness of a school scientific society might still further be increased by calling in the assistance of scientific men to deliver lectures which should be open not merely to the members, but also to a wider circle. The literary Society at Eton has, we believe, adopted this plan on very many occasions; recently it will be remembered that Mr. Gladstone addressed the society on Homer. Mr. Russell's lecture is a full one, and on the lines which it follows, a useful one. "Geometry is a pure science, gives logical training, is a discipline of thought, is an instrument of human culture, and has high educational value. But geometry is equally the development of a method pervading nature; its mastery gives man a power to govern matter. The training which enables him to comprehend the mechanism of the universe, enables him also to make creations of his own in harmony with those greater designs of which his own are but a small portion. These two uses of geometric education the one purely gymnastic, the other practical and technic, may be so combined that each shall aid and not impede the other. The order, number, and measure which pervade the universe can be easily brought within the scope of elementary education, and so form the fit preparation for scientific observation and experiment in later life, by means of which the standard of application of abstract truths to matter and events in human life are determined and made familiar. But the one learning cannot be too soon begun, nor the other too long continued, and each is a material aid to the other." This extract shows the author's views, which he has worked out in some detail. Starting from the Greek geometry, he passes on to useful geometry: its applications to land-measuring, trigonometry, navigation. He touches also on numbers, goes on to symmetry, harmony, melody, then to light, shape, and shadow. He closes with a chapter on matter, force, and motion. To sum up, the whole furnishes a quantity of illustration from an eminent practical man, which is likely to be profitable to teachers in search of such illustration—to allure the "what's the use of it?" boys who form a part of every mathematical master's geometrical classes.

Die Geologie der Gegenwart. Dargestellt und beleuchtet von Bernhard von Cotta. Fünfte umgearbeitete Auflage. (Leipzic: J. J. Weber, 1878.)

THE appearance of a fifth edition of von Cotta's well-known work is a sufficient proof of its popularity—a popularity which, in spite of some unfortunate drawbacks to its usefulness, we cannot but regard as being well deserved. Since the first appearance of the volume in 1866 it has been steadily growing in bulk, and in the present edition the author has brought his work up to date by noticing the principal contributions which have recently been made to geological science. Among such additions we may point to his notices of the method of study of rocks by the means of the microscope, of the new classification and nomenclature of the stratified rocks suggested by Carl Mayer, of the results of the *Challenger* expedition, of the latest speculations on the causes of volcanic activity and the nature of meteorites, and of Croll's theory of the recurrence of glacial periods. The coloured frontispiece now added to the work, we can scarcely regard as an improvement, seeing that it tends to perpetuate those views of the restriction of certain classes of volcanic products to distinct geological periods, which, though so frequently insisted upon by German petrographers, do not appear to be sustained by extended observation in the field.

Ocean and Her Rulers. By Alfred Elwes. New and Revised Edition. (London: Griffith and Farran, 1878.)

Under the Red Ensign. By Thomas Gray. (London: Simpkin, Marshall, and Co., 1878).

THESE are two good books, each in its way. The former is a narrative of the nations which have from the earliest ages had dominion over the sea, comprising a brief history of navigation down to the present time. It is evidently intended for boys and is likely to interest the more thoughtful of them and send them to works which will give a more detailed account of the peoples whose exploits by sea are told, and lead them to take an interest in geographical discovery. The reading is rather miscellaneous and unconnected, and the information sometimes undigested, but as a whole the book is useful and interesting.

Mr. Gray's booklet is one that will prove thoroughly useful to parents intending to send their boys to sea, as well as to the boys themselves. Mr. Gray knows well what he writes about, and the information and advice he gives as to the choice of a sea-life as a calling, how to get a boy launched into it, what kind of ship to choose, how the boy should conduct himself, what books he should read, and a multitude of other points are admirable. We are glad to see that among the books he recommends a large proportion are standard scientific works.

Memoir of the late Alfred Smee, F.R.S., by his Daughter. With a Selection from his Miscellaneous Writings. (London: George Bell and Sons, 1878.)

MR. SMEE was in many respects a remarkable man, and this readable memoir by his daughter will, we doubt not, be acceptable to those who knew him personally or through his works. An Appendix contains about forty papers, letters, pamphlets, &c.; these occupy quite two-thirds of the volume.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

An Intra-Mercurial Planet

WITH reference to the important announcement, by telegram, of the discovery by Mr. Watson of an intra-Mercurial planet during the late eclipse of the sun, it may be worth remarking that the position of θ Cancri agrees very well with that given in the telegram published in NATURE, and that there may be a possibility that the object observed is in reality this star. The position of the suspected planet recorded by Mr. Watson is R.A. 8h. 26m., and N.P.D. 72°; the apparent place of the star, computed from the mean place given in the new Nine-Year Catalogue for 1872, January 1, is, for July 29, R.A. 8h. 24m. 40s., and N.P.D. 71° 29′ 40″. The magnitude of this star is, however, smaller than that given by Mr. Watson, that in the British Association Catalogue being 5½, and that in Argelander's

Uranometria Nova 6. This discrepancy may very easily occur in the hurry of such a sensational observation, as on these occasions the time at the disposal of the observer is so limited.

Royal Observatory, Greenwich, August 3 G. B. AIRY

Floating Magnets

I HAVE no intention of discussing the beautiful experiments of Prof. A. M. Meyer on floating magnets; but as a privately-expressed opinion of mine has appeared in NATURE, vol. xviii. p. 260, I feel bound to defend it. The mutual repulsion of the vertical floating magnets varies nearly inversely as the fourth power of the distance at great distances, and nearly inversely as the square at small distances. The horizontal attraction of the magnet, held vertically over the water, varies nearly inversely as the fourth power at very great distances. At a certain moderate distance it reaches a maximum, and close to the centre it varies directly as the distance. It is easy to see that variations of the magnetisation of the lengths of the magnets, and of the distance of the large magnet from the surface of the water, may render configurations stable which would, under different conditions, be forms of unstable equilibrium. Prof. Meyer thinks that the configuration can never be stable. It is easy to see that it is a form of equilibrium, and in fact that any given size of hexagon will be brought into equilibrium by placing the large magnet at a suitable distance. It may, therefore, be in equilibrium when the floating magnets are on the circle of maximum attraction of the fixed magnet. But, in this case, the equilibrium is stable; for work would be expended in altering in any way the position of any one of the floating magnets. If this one is carried away from the others they repel it less, and it will be brought back; if it is carried nearer to the others they repel it more, and again it will be brought back.

The nature of equilibrium where there are several degrees of freedom may be illustrated by considering a tract of country upon which water can run. The hollows are positions of stable equilibrium; the summits and passes (saddles) are positions of unstable equilibrium. Then, if any one speaks of the former as more or less stable (as Prof. Meyer does of stable configurations), he may be understood as having reference to the curvature of the hollow, or to its level, or to some vague and mixed characters. It is very easy to understand why the form should be difficult to produce or maintain. It is because the floating magnets are in this case at much greater distances from the centre than when they assume the form Hence, the potential energy of the former configuration is much greater than that of the latter. The reverse is the case with and , and still more so with and , and so with greater numbers of magnets.

C. S. PIERCE

Mons. A. Cavaillé-Coll on Musical Pitch, the French Diapason Normal, Scheibler's Tuning-Forks, &c.

IN the course of my researches on musical pitch, with the view of discovering the source of the discrepancy between Appunn's and Lissajous's measurement of the French diapason normal, I have had the good fortune to enter into correspondence with M. Aristide Cavaillé-Coll, the celebrated Parisian organ-builder, and in his long and obliging answers to my inquiries he has communicated some facts which I have thought it important, with his permission, to lay before the readers of NATURE, as far as possible in his own language.

Scheibler, and the Persistency of the Pitch of Tuning-forks.—M. Cavaillé-Coll had the advantage of personally knowing Heinrich Scheibler, silk manufacturer, of Crefeld, near Düsseldorf, who died November 20, 1837. Scheibler's experiments on tuning, with which I had long been acquainted, are the most important hitherto made; but I had feared that his wonderfully accurate tuning-fork tonometer was irrecoverably lost. I find that M. Cavaillé-Coll is fortunate enough to possess one, and Herr Amels, of Crefeld, another, that is, a series of fifty-six forks, proceeding by degrees of four beats in a second, from A 220 to A 440 double vibrations in a second, which last was adopted by the Stuttgart Conference in 1836 as the best normal pitch. This was chosen by Scheibler as his standard, because it was the mean of the Viennese grand pianos in his day. Of him M. Cavaillé-Coll says:—

"M. Scheibler n'était pas un savant, mais, en s'appuyant sur les expériences faites par Sauveur en 1701 pour la détermination d'un son fixe, il était arrivé par ses patientes recherches à créer, en 1834, un tonomètre différentiel de la plus rigoureuse exactitude et qui n'avait pas été fait avant lui."

Of the exactness with which Scheibler worked M. Cavaillé-Coll gives the following remarkable proof, which is at the same time a proof that tuning-forks will preserve their pitch for at least twenty-eight years; so that there is no reason to suppose that, when properly protected, they will not form a lasting record. This was a point on which I dwelt much in my letter to M. Cavaillé-Coll, because it has been often thought that they might vary considerably. See Zantedeschi (*Sitzb.* Vienna Acad. vol. xxv., year 1857, p. 172), whose conclusions I believe to be erroneously based. M. Cavaillé-Coll says, in his first letter (January 24, 1878):—

"En 1862, j'ai eu l'avantage d'assister aux expériences faites par M. Léon Foucault pour la détermination expérimentale de la vitesse de la lumière. Ce savant expérimentateur, que la mort a enlevé à la science en 1868, se servait, pour mouvoir son miroir tournant, d'un petit tambour mis en mouvement par une soufflerie et un régulateur de pression que je lui avais établis; laquelle turbine devait faire 400 tours à la seconde. Or avec cette vitesse, la turbine faisait entendre un son d'axe dont le nombre de vibrations correspondait au nombre de tours." In a subsequent letter (February 8, 1878) M. Cavaillé-Coll adds:—"M. Léon Foucault, bien qu'il fit construire ses instruments par les premiers constructeurs, était toujours obligé de les vérifier et de les rectifier lui-même pour arriver à la régularité de marche qu'il avait en vue d'obtenir."

"Pour mesurer la vitesse de la turbine, M. Léon Foucault avait imaginé un moyen nouveau que je vais essayer de décrire. D'abord une pendule de précision, construite par l'habile constructeur Froment, mettait en évidence une roue dentée de 400 dents, laquelle faisait un tour entier par seconde. Ensuite, la turbine était disposée de manière à réfléchir un rayon lumineux du miroir tournant sur les dents de la roue. Or la coincidence des rayons lumineux avec le passage des dents de la roue de la pendule permettait de reconnaître, à l'immobilité apparente des dents de cette roue, que la vitesse de la turbine était alors exactement de 400 tours par seconde." This description is necessary to understand the extreme delicacy of the test of Scheibler's work, which follows. "Un jour que j'assistais à une de ses observations, M. Léon Foucault me dit: 'Si nous avions un diapason exactement accordé de 400 vib. par seconde il devrait se trouver d'accord avec le son d'axe de la turbine? Sans rien dire à M. L. Foucault, je cherchai dans mon tonomètre de Scheibler un diapason de 400 vib., et l'ayant comparé avec le son d'axe de la turbine, je le trouvai si exact que je fus émerveillé de constater que par des moyens différents et à plus d'un quart de siècle de distance ces deux savants expérimentateurs avaient atteint avec la même perfection la détermination d'un son fixe donnant exactement 400 vib. par seconde. Cette circonstance est venue confirmer dans mon opinion que le tonomètre de H. Scheibler pouvait être regardé comme un instrument de la plus haute précision." M. Cavaillé-Coll concludes:—"Dans mon opinion le diapason conserve le même ton à la même température. Il n'y a que l'altération du métal lui-même qui puisse faire changer le ton; mais si l'on prend les soins nécessaires pour préserver les diapasons des influences climatériques, comme le faisait H. Scheibler, on peut être à peu près certain qu'ils conservent le même ton."

Improvements in the Siren, Bellows of Precision, Double-Action Counter.—M. Cavaillé-Coll was also personally acquainted with M. le Baron Cagniard de Latour, and was "initié à ses travaux." He calls him "un des plus savants acousticiens français du siècle présent," and says he is "sans contredit le véritable inventeur de la syrène;" adding, "la date de la création de ce merveilleux instrument, qui se trouve aujourd'hui dans tous les cabinets de physique d'Europe, remonte à l'année 1819;" and he complains that Helmholtz should have mentioned Seebeck's first, even on the score of simplicity of construction, as it was invented so long afterwards.

The difficulty of using the siren for the exact determination of pitch is ordinarily very great, so that observations made by it without proper precautions are, as a general rule, defective. The causes of error (besides imperfect workmanship) are—1. The difficulty of estimating with precision at what time the continually rising pitch of the siren note reaches the height of the continuous tone with which it is compared, precise equality of pitch (as in the example just given) being always extremely difficult to attain, and also to verify, except under the most favourable circumstances, and with the siren the circumstances are most unfavourable; 2. The difficulty of obtaining a blast under constant pressure to make the tone of the siren continuous; and 3. The difficulty of comparing the counter of the rotations of the siren's disk with the seconds counter. Now M. Cavaillé-Coll, as an experienced, ingenious, and scientific organ-builder, turned his attention in the first place to the second difficulty, which when overcome would obviate the first. It is clear that if the tone of the siren could be indefinitely sustained at the same precise pitch, it could be completely compared with another tone either by unison or by beats. In 1863 (*Comptes Rendus*, vol. lvi. pp.309-443) M. Cavaillé-Coll invented a "soufflerie de précision" for giving a constant blast, applicable not only to the siren but to many other scientific instruments. The complete bellows, such as he furnished for the physical laboratory of the Sorbonne, is expensive (about 80*l*.), but he has arranged "un petit modèle de soufflerie de précision pour des expériences d'acoustique, et que j'estime à 500 fr.," 20*l*. (not including the siren), inclosed in an oak case about 27½ inches long, 17¾ inches wide, and 32½ inches high, and therefore of most convenient dimensions for an experiment. "Cette soufflerie," he says in his letter of February 8, 1878, in answer to my inquiries, for the small model is not described in the *Comptes Rendus*, "est mise en jeu par une pédale en fer à la portée de l'opérateur. Au-dessus de ce bâti est un grand régulateur de pression communiquant avec un sommier de 13 notes sur lequel on peut monter toute espèce de tuyaux; de chaque côté du grand régulateur et communiquant avec lui, j'ai disposé deux petits régulateurs angulaires à poids curseurs, avec leurs sommiers sur lesquels on peut monter soit la syrène, soit deux tuyaux pour l'étude des battements. Sur le sommier du grand régulateur de 13 notes j'ai placé une série harmonique de tuyaux à bouche du ton de 8 pieds à partir du 3ème (*Ut* de 2 pieds), et composé de 13 tuyaux d'étain exactement accordés, donnant les sons 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15 et 16. Bien que les trois premiers tuyaux de la basse manquent, cette série des sons harmoniques naturels permet néanmoins de faire de bonnes expériences sur le *timbre*, et sur les *sons résultants*." I have given the description of this instrument at length, because it is evidently precisely what is wanted for acoustical experiments. The ordinary laboratory blowing apparatus I have found quite useless for experiments on pitch and beats. By means of these constant action bellows it is possible to maintain any tone on the siren for many minutes, and hence the two first difficulties are overcome. The third difficulty (of counting), not to mention insufficient accuracy of workmanship in the siren, still remained.

"En général," remarks M. Cavaillé-Coll in his letter of February 8, "l'exécution de ces appareils [les syrènes de commerce] laisse beaucoup à désirer. Quand j'ai voulu faire des observations exactes, j'ai dû faire retoucher l'appareil avec beaucoup de soin par un de mes employés; mais après avoir obtenu la régularité du mouvement de la syrène, j'ai rencontré une nouvelle difficulté pour marquer exactement la durée de l'observation au moyen d'une pendule à secondes. C'est alors que j'eus l'idée de compléter la syrène par un compteur à pointage, que me permet d'embrayer du même coup le compteur de la syrène et le compteur à secondes, de manière à bien préciser le point de départ et le point d'arrivée de l'observation. Je construisis à cet effet un petit appareil en bois que je conserve dans mon cabinet comme souvenir historique de mes essais, et qui fonctionnait fort régulièrement. Plus tard j'ai composé le dessin d'un appareil plus élégant, pouvant se fixer sur l'armature de la syrène, et j'en ai confié l'exécution à l'opticien qui avait établi ma syréne, espérant que cela pourrait lui donner l'idée d'en construire de semblables pour le commerce; mais ce petit travail fut mal construit, et ce n'est que longtemps après que j'ai pu faire exécuter sous mes yeux, dans mes ateliers, l'instrument que j'ai montré, et qui est encore unique en son genre."

By means of this complete regeneration of the siren, M. Cavaillé-Coll says, in his memoir in the *Comptes Rendus*, that he has been able to "faire des expériences qui ont duré plus de dix minutes, avec une telle exactitude, qu'en répétant plusieurs expériences les résultats n'ont jamais varié que de quelques vibrations sur 50,000 environ." In his letter he says:—"J'ai fait à cette époque (1858–9) avec mon appareil, plusieurs observations dont la moyenne concordait avec les nombres constatés au tonomètre de Scheibler."

Pitch of the French Diapason Normal, and how Lissajous determined it.—As regards its pitch, M. Cavaillé-Coll has carefully compared the French diapason normal with Scheibler's 440 double or 880 single vibrations, the accuracy of which, after the striking proof already given of Scheibler's exactness, admits of no question. He says, on January 24:—"J'ai trouvé alors, que notre diapason normal de 870 vib. simples, donnait exactement 871·75 vib. par seconde, d'où il résulte que notre diapason, au lieu de 435 vib. doubles, donnent 435·875 vib., soit près d'une vibration sonore en plus que le chiffre de 435 vib. assigné par le rapport de la commission."

This is a most important piece of information. Copies of the French normal are easily procured, but they almost all vary by some vibrations in ten seconds, even when costing 20 to 35 francs. I have given means of making forks of 440, 256, 512 vibrations, according to Scheibler, and hence also of the exact pitch of the French normal, to Messrs. Valentine and Carr, 76, Milton Street, Sheffield, successors to, and long workers with, Mr. Greaves, from whom physicists can be pretty sure of getting any pitch they like, within a few tenths of a vibration, for 3*s*. a fork, small size, but sounding 20 to 30 seconds. I mention the names of these workers because people do not generally know where to go for such work, and it is not safe to give orders second-hand through the music-sellers. For larger forks and greater accuracy, and of course much greater cost, perhaps Mr. Ladd, of Beak Street, would be the best person to consult, but he uses Koenig's pitch. Messrs. Valentine and Carr can also make large forks if required. Time must also be given. To make a fork with perfect accuracy is often two or three weeks' work, for after filing, the pitch rises, and the fork has to rest three days at least before it can be tried again. This was Scheibler's experience, fully confirmed by my own.

Now, my observations on Appunn's instrument, just finished, but not reduced, show that his numbers are in excess about one per cent., a little more or less. His tonometer, when in perfect condition, gave the pitch of Broadwood's copy of the French normal, presented by the French Commission in 1859, as 439 exactly. As Koenig's forks showed perfect intervals when measured by this tonometer, we may take it as almost, if not quite, exactly correct that the acceleration of the beats in that instrument is uniform throughout. This would show that Appunn's numbers should be reduced in the proportion of 435·875 to 439, in order to obtain Scheibler's pitch, which is probably as accurate as we can hope any measurement to go. But I have since found that Broadwood's copy was not quite accurate, and that the best approximate rule is to throw out 1 in 123 vibrations. Thus the fork of the Liceo Musicale of Bologna, sent officially to the Society of Arts in 1869, and measured "graphically" at Bologna as 443·89, but measured by me with Appunn's tonometer as 447·2, would be 443·6 by Scheibler's pitch, and this agrees with actual measurement by Scheibler's 440. Again, by Appunn's tonometer, Koenig's Ut_3 was 258·4, which, corrected as above, gives 256·3. Now the measurements of Koenig's Ut_3, by Prof. Alfred Mayer and Prof. McLeod, with their own special instruments, give the pitch nearly as 256·3, and this agrees with actual measurement by one of Scheibler's own forks given me by M. Cavaillé-Coll.

For some time I had vainly endeavoured to learn the method employed by M. Lissajous to determine the pitch of the diapason normal, which I regarded as of great importance in the history of practical music. I am indebted to M. Cavaillé-Coll for the following information (on February 8):—

"M. Lissajous s'est servi de la syrène de M. Cagniard de Latour, mise en jeu par ma soufflerie de précision, munie d'un régulateur de pression, pour déterminer le ton du diapason normal. Quant au compteur à secondes dont j'ai armé ma syrène, je ne pense pas que M. Lissajous en ait eu connaissance lors de la détermination du diapason normal, et c'est peut-être à cela qu'est dûe la petite erreur que j'ai constatée par mes expériences à la syrène et par comparaison avec le tonomètre de Scheibler." "Je n'ai pas assisté," he had written, on January 24; "aux expériences de M. Lissajous pour la détermination du ton normal, vu qu'à cette époque nous n'étions pas d'accord sur

l'abaissement du quart de ton qui a été fixé par la commission. Je voulais, avec quelque raison, je crois, fixer le ton du diapason à 888 vib. qui avait pour base l'*ut* de 32 pieds égal à 33 vib. par seconde, le *la* géometrique = à 880, et le *la* tempéré 888, ainsi que je l'ai expliqué dans la petite brochure, 'De la Détermination du Ton Normal ou du Diapason pour l'Accord des Instruments de Musique,'" published originally in *L'Ami de la Religion*, February 6, 1859, before the normal La was fixed. At the close of this paper M. Cavaillé-Coll says, in favour of 888 v. s., besides his present remarks, "Ce nombre, qui se trouve de 8 vibrations plus élévé que le *la* normal du congrès de Stuttgard et de 8 vibrations plus bas que le diapason de l'Opéra de Paris [en 1857] aurait, suivant nous, le mérite, s'il était adopté, de concilier les exigences de la science physique et les besoins de l'art musical." The peculiarity that C 264 gives a just A 440 = $\frac{5}{3}$ × 264, and a tempered A 444, has been productive of some confusion. The committee called together by the Society of Arts in 1859 recommended the Stuttgart pitch A 440, which they considered would give C 528, whereas on equal temperament it would give C 523¼. But they made C 528 their standard, which would give the tempered A 444, and the Society of Arts commissioned the late Mr. J. H. Griesbach to make them such a fork, for which he employed the instrument now in room Q of the South Kensington Museum, and to this he endeavoured to make an equally tempered A. His results in place of C 528, A 444, were, when reduced from Appunn's to Scheibler's standard, C 535 and A 446, which do not even agree with each other, for his C requires an A 450, and his A requires a C 530, both being rather sharper than was intended. In the organ of the cathedral of St. Denis M. Cavaillé-Coll measured the pitch as A 444·25, by means of the siren, but before the application of his bellows of precision. The Bolognese fork, already mentioned as being nearly A 444, was also measured at Bologna by the siren, but the result is not stated in the report preserved by the Society of Arts.

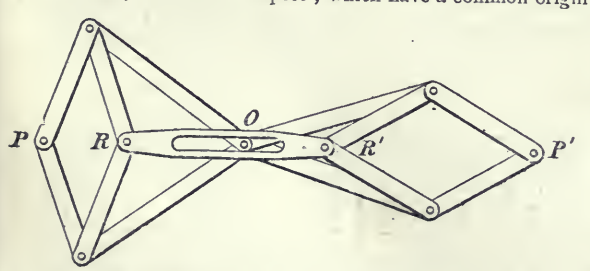
As regards the introduction of equal temperament into France, M. Cavaillé-Coll informs me that up to 1834 their house tuned on the old mean-tone principle, but that subsequently to 1834 he has consistently laboured to carry out the equal temperament. He thinks, however, that equal temperament was used for pianos before that date. I may mention that the change was made at Broadwood's, in London, between 1841 and 1846. That at the first Great Exhibition of 1851 in London, only one organ (by Schulze) used equal temperament, and that at least three organs had not adopted it a year ago (St. George's, Windsor, Turvey Abbey, and Norwich Cathedral).

Kensington, W., July 13 ALEXANDER J. ELLIS

Peaucellier Cell

THE following application of the Peaucellier Cell may possibly interest some of your readers. The object of this arrangement is to make two points—one on each side of a lens—move in such a way as always to remain at conjugate foci.

In the accompanying wood-cut P, R, and P′, R′, are the poles of two cells, alike in all respects, which have a common origin



at O; and the poles R and R′ are connected together by a bar with a slot in it, through which the pin which forms the pivot at O passes. Then if P, R, P′, R′, are constrained to keep in a straight line, P and P′ can approach or recede from O, only in such a way that, if there is a lens of proper focal length at O, P and P′ will always be conjugate foci.

This is easily proved thus:—

Suppose P O $= p$, P′ O $= r'$,
R O $= r$, R′ O $= p'$,
and the bar R R′ $= l$.

From the property of the cell,

$$r = \frac{k}{p} \quad r' = \frac{k}{p'}, \text{ where } k \text{ is a constant},$$

$$l = r + r' = k\left(\frac{1}{p} + \frac{1}{p'}\right)$$

$$\frac{1}{p} + \frac{1}{p'} = \frac{l}{k}.$$

Hence, if $\frac{k}{l}$ is the focal length of the lens, P and P′ are conjugate foci.

Mr. Francis Galton wanted to use the above arrangement, but found he could not get sufficient range unless the cells were made of unwieldy size. HORACE DARWIN

The Microphone

IN reproducing the experiments first made by Prof. Hughes with the microphone, I interposed in the circuit a galvanometer, and first found with the battery used (made with three small glass cones, as used by Prof. Hughes), when the microphone was not in the circuit, the current was sufficiently strong to deflect the needle to 40°. Now interposing the microphone, made of mercurised carbon peas in a small glass tube, it acted well as a transmitter only when the pressure on the carbon peas was so adjusted that the needle of the galvanometer stood about 15°.

When the pressure was very slight and the resistance to the current so great that the needle swung only to 5° or 8°, then the "continuous distant waterfall roar" of the telephone was plainly audible. The slightest sound of the voice in the room would produce the painful *pat*, *pat*, indicating an intermittent current and not a continuous one of varying intensity.

This "distant waterfall roar" emitted by the telephone, not unlike the "murmur of the sea-shell," was in all respects similar to the sound familiar to those who have attempted to use a telephone whose line was greatly affected by the induced currents of a number of proximate telegraph lines in active use. When the pressure of the carbon peas was so slight and consequent resistance great, the vibrations of the air in the room, when most quiet, so increased and diminished the resistance to the electric current as to cause the incessant tremor of the tympanic plate of the telephone, and thus rendered audible the constant murmur.

Among many other methods I tried a torsion pendulum, made by suspending, with a small cotton cord, a double cone of mercurised carbon an inch long, between two pieces of carbon less than an inch apart, to which the connecting wires were attached. The pressure was regulated by the torsion of the cord. In this simple manner any required delicacy was easily attainable.

Vanderbilt University, Nashville, Tenn., July 1 WM. LEROY BROUN

OF the many ingenious forms the microphone has taken—and I believe I am acquainted with most of them—none is, I think, more efficacious than the one I offer for your inspection. The jarring sound in the principal instruments in use, which, by vibration, may emanate from passing vehicles, &c., is entirely obviated, and the sound of a piece of fine silken thread, or the now well-known tramp of a fly, is heard with double the distinctness of any microphone I have listened to.

It consists simply of a cup and ball of carbon, the cup being fastened to a small piece of board, and one of the insulated wires attached to it in the usual manner, while the other is carried through the bottom of the cup sufficiently far to touch the ball without disturbing it in its socket.

From this little instrument I have obtained the most satisfactory results, and have heard distinctly that which I had to strain my hearing to catch before. Unless my "idea" is already anticipated, might I ask you to make it known to your numerous readers? GERALD B. FRANCIS

23, Bessboro' Gardens, S.W., July 24

A Simpler Form of the Phoneidoscope

MOST of your readers will be familiar with Messrs. Tisley and Spiller's beautiful instrument, known as the phoneidoscope. In using it, however, I have found certain defects, which my improvement on it is intended to obviate.

These are :—

1. That it is sometimes difficult to adjust the angle of the film so as to get the best light on it.

2. It is impossible to vary the distance of the film from the mouth so as to use both loud and faint sounds.

3. There is no means of adjusting the tension of the film.

My phoneidoscope, which is free from these defects, and which I have found to work exceedingly well, simply consists of the hand and some soap-suds. The forefinger and thumb being bent so as to form a circle, a soap film is drawn across them with the other hand. By turning the wrist, the angle which the film makes with the direction of the light can be accurately adjusted.

A motion of the elbow alters the distance from the film to the mouth, and by slightly separating or bringing together the finger and thumb, the tension of the film can be exactly regulated so as to give any degree of sensitiveness that may be desired.

The extra delicacy obtained by this adjustment much more than counterbalances the absence of the tube and mouthpiece.

Pixholme, July 30 J. E. H. GORDON

Spectrum of the Electric (Jablochkoff) Light

I WOULD suggest that when your readers visit Paris they should take their pocket spectroscopes. They will find a very interesting spectrum in the electric lamps now being used for lighting some of the principal public places in the city. One might have expected to have found from the brilliant spark inclosed in a white opaline globe a continuous spectrum such as is afforded by the voltaic arc. But the contrary is the case. The Jablochkoff candle now in use in Paris, even when viewed by one of Browning's small pocket instruments, presents a very complicated and highly interesting spectrum. I had no chart with me for comparison, nor did I, as I intended subsequently, make even a rough record of the spectrum; but speaking from memory, I may say that several lines in the blue and green were very marked and distinct, and, in fact, the whole spectrum was traversed by bright and dark lines. I thought, probably, some of these dark lines might be due to absorption by the white opaline glass globe, but I have tested several specimens of this white glass, and I find it does not alter in any way (except by generally reducing its brilliancy) a continuous spectrum, nor does it change the character of the solar spectrum. We must, then, turn to the light itself and to the atmosphere surrounding it for the cause of these phenomena. I believe that in a chemical sense there is no difference between the ordinary electric arc between the carbon points and the arc of the Jablochkoff candle, except that between the carbon points of the latter is a rod of kaolin, which has, I think, a calcium base. This kaolin is intensely heated by the current, and is volatised at the same rate as the carbon rods by the alternative current which this form of candle requires. The light, therefore, is a combination of the electric and the lime light, the current taking the place of the oxy-hydrogen elements. The surrounding atmosphere will be the same in both cases, but the products of combustion will obviously be different, and partly so from the composition of the kaolin. Still, I confess that I cannot suggest the cause of this complicated spectrum, and I hope that some observers who have more accurate means and more experience will give us the *rationale* of the phenomena.

I may say that there is not at present any Jablochkoff candles to be seen in use in this country, but in the course of two or three weeks they will be introduced into a large establishment, where excellent means of observation will be afforded.

Royston House, Tottenham, July 27 E. WALKER

P.S.—Since forwarding the above I have observed the Loutin light now on view at the Gaiety Theatre. The spectrum is somewhat similar to that of the Jablochkoff light, but much less distinct. This is probably owing to the circumstance that at the Gaiety the arc is inclosed in a small opaline globe, which is itself encased in an ordinary ground glass lanthorn (the proper lamps came to grief in transit), this diffusive ground glass causing, by overlapping, the indistinctness. Still there are absorption bands and some remarkable bright lines, which, with my small pocket instrument, I will not attempt to define. Nor, as it is a matter for careful observation, will I speculate further than to suggest—seeing that the Loutin light is from the carbon points only—that the white opaline glass may exercise a selective power over the spectrum given by this high state of incandescence which it does not in ordinary cases, and may give us also, to an extent, the actual wave due to a particular element rather than its obscuration. If so the Loutin light should differ somewhat from the Jablochkoff light, being deficient of the kaolin. E. W.

The Meteor Showers of July

THE prominent shower of *Aquarids* mentioned in my letter in NATURE, vol. xviii. p. 356, had become extremely feeble on July 31 and August 1, for of 136 shooting stars seen on those nights only three or four were conformable to that radiant point which, from a careful re-examination of all the paths recorded from it, is situated exactly at 341°—13°, near δ Aquarii (from fifty-four meteors).

Between July 26 and August 2 403 shooting stars were recorded here, of which no less than sixty-three (including one perfectly stationary) belonged to a very sharply-defined radiant near χ Persei, at 32° + 53°. Fourty-four of these were noted on the three nights, July 30-31 and August 1, when the shower appeared to attain its full intensity. The meteors were very swift with short paths (of about 7°), and almost invariably left streaks of 3° or 4°. They were shorter and less bright than the August *Perseids* at 43° + 58°, and in strong contrast to the long, slow meteors of *Aquarids* seen on the few preceding nights. This very rich stream at 32° + 53° has escaped previous detection, for, being near the date and position of the August *Perseids*, there can be no doubt that its meteors have in past years been attributed to that well-known shower, and given it an undue extension of period. The two radiants are, however, quite distinct, and it is now easy to explain the statements of some observers that there are many *Perseids* visible during the latter part of July. I believe that but few of the old *Perseids* can be seen before August 6 or 7. My own observations this year show that only seven or eight were seen before August 2, though I watched that region in which the radiant lies very carefully, and noted 400 meteors amongst the constellations there!

Thus at the end of July we may expect two special meteor showers: one of *Aquarids*, at 341°—13°, the other of *Perseids*, 32° + 53°. The former comes to a maximum two or three nights earlier than the latter, which may be called the "*Perseids* II.," in order to distinguish them from the old *Perseids* of Heis.

Ashleydown, Bristol, August 3 W. F. DENNING

The Rainfall of Brazil and the Sun-Spots

AN examination of the scanty records of rainfall obtainable in Brazil proves that the relation between rainfall and sun-spots, which has been pointed out in India by Dr. Hunter and others, holds good for the inter-tropical portion of Brazil.

The only stations from which I have been able to obtain records for a series of years are the city of Fortaleza (better known in Europe as Ceará), in latitude 3° 42′ S., and Rio de Janeiro, in latitude 23′ S. The rainfall of these two stations is shown in series in the following table :—

Series of Years in the Cycle of Eleven Years.	Average relative Annual Number of Sun-Spots, 1811-1875.	Mean Annual Rainfall of Ceará, 1849-1877.	Mean Annual Rainfall of Rio de Janeiro, 1851-1877.
		March.	June.
Minimum Group. 11th Series ...	16·3 } 12·6 mean.	1429·3 } 1342·2 mean.	1134 } 1032·6
Minimum Group. 1st & 2nd Series	10·8	1298·6	986
3rd and 4th Series	48·6	1493·8	1039·2
5th ,, 6th ,, ...	88·3	1587·7	1011·2
7th ,, 8th ,, ...	65·3	1608·1	1355·3
9th ,, 10th ,, ...	38·5	1252·6	1139·3
11th ,, ...	16·3	1429·3	1134

The northern provinces of Brazil outside of the Amazon valley, and notably that of Ceará, are subject to severe and prolonged droughts, of which that of 1877 is one of the most terrible on record. The annals of Ceará make mention of thirty years of drought since 1711, many of which, however, were only partial or slight, and many of which occurred in groups of consecutive years, there being one group of five dry years, another of four, and four groups of two years each. Twelve notable floods are also recorded since 1776. The droughts and floods are distributed as follows, among the groups of the years of the sun-spot cycle, proposed by Dr. Hunter :—

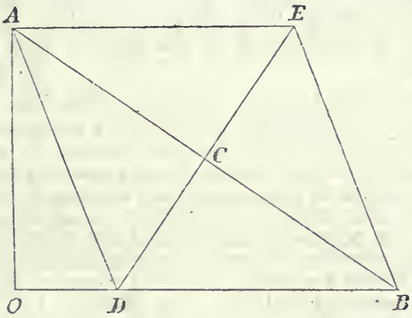
	Droughts.	Floods.
Minimum Group (11th, 1st, and 2nd Series)	13	2
Intermediate Group (3rd, 4th, 9th, and 10th Series) ...	10	4
Maximum Group (5th, 6th, 7th, and 8th Series) ...	7	6

Of the seventeen cycles of eleven years, between 1711 and 1877, only three have no record of one or more dry years. The great droughts were those of 1722, 1778, 1792, 1825, 1845, and 1877, of which four occurred in the minimum group, one commenced in that group, but culminated in the intermediate group, and one was confined to the latter group.

Rio de Janeiro, June 12 ORVILLE A. DERBY

The Cell of the Bee

THE following simple construction shows in one figure all the elements of a cell of a honey-comb. On two rectangular axes take OA and OB equal to the side and diagonal of a square. Join AB and bisect it in C. Draw CD normal to AB. Join AD, and complete the rhombus whose sides are AD, DB. Then if OA be a side of the hexagon, ADBE is one of the three equal planes forming the trihedral angle which closes the cell. The three short diagonals DE meet in the vertex of the cell, and are



normal to each other. The three long diagonals AB form an equilateral triangle. OD is the height of the vertex above the hexagonal face of the prism. AED is the angle which the axis of the prism makes with each of the diagonals DE. ADO is the angle which the axis of the prism makes with each of the edges of the trihedral angle. The diagonals DE and AB are in the ratio of the side and diagonal of a square. Such a cell contains a maximum volume with a minimum surface.

Bardsea EDWARD GEOGHEGAN

OUR ASTRONOMICAL COLUMN

THE REPORTED OBSERVATION OF "VULCAN."—In the telegram received from Mr. Lockyer relating to the solar eclipse which appeared in NATURE last week (p. 353), and which, like many other similar messages, had suffered in course of transmission, mention was made of Prof. Watson's observation of an object of $4\frac{1}{2}$ magnitude in R.A. 8h. 26m., and declination 18° 0′ north, which was neither a known planet nor a star. θ Cancri, a star of the fifth magnitude, is less than a degree from this position, but the observer would doubtless be aware of its presence. A telegram to the same purport was received by M. Mouchez, the director of the Observatory at Paris. By the formula deduced by Leverrier from the observations of suspicious objects in transit across the sun's disc, if the indeterminate k be put $= 0$, the elongation in longitude of his hypothetical body from the sun's centre at the time of totality at Prof. Watson's station would be 5°·9 eastward, and if $k = -1$, 9°·5 westward, neither of which, it will be seen, accords with the position given in the telegram. The fourth-magnitude star, δ Cancri, must have been within the limits of the coronal surroundings of the sun, and was only just beyond them during the total eclipse of July 28, 1851, when no observer, to our knowledge, remarked the star. In the instructions for observing the eclipse issued from the United States Naval Observatory, Washington, and prepared by Prof. Harkness at the instance of Admiral Rodgers, the superintendent, it is remarked: "As the truth of Leverrier's discovery of an apparently unexplained motion of the perihelion of Mercury is now established beyond all doubt, it is important to renew the search for an intra-Mercurial planet or planets." And to facilitate the work of such astronomers as might institute a search with considerable telescopic power, a chart was appended to the instructions showing every star so large as the seventh magnitude in that portion of the heavens occupied by the sun at the time. This chart extends from 7h. 32m. to 9h. 40m. in right ascension, and from 11° to 26° in declination. θ Cancri, the only star which appears near the position indicated for Prof. Watson's object, is marked on the chart as a sixth magnitude, which is the estimate of the *Uranometria* and *Durchmusterung*, but the star has been occasionally rated a fifth magnitude as in the first Radcliffe Catalogue, wherein particular attention was paid to the brightness of the stars. This is only a half-magnitude below Prof. Watson's estimate, but it remains to be seen from further intelligence whether there was any possibility of the star having been the object really noted; if it were separately remarked, or if the observed position does not admit of such change as would be necessary for identification, then it may truly be said that the American astronomer will have rendered the occasion of this eclipse a memorable one in the history of the science. Leverrier's confidence in the existence of an unexplained motion in the perihelion of Mercury and the necessity of accounting for it, by admitting the presence of matter in some form within the orbit of the planet, continued undiminished up to the time of his decease. One of his last communications to the writer of these lines was upon this subject.

THE LUNAR ECLIPSE ON AUGUST 12.—The eclipse of the moon on August 12 is the only one that will be wholly visible in this country until the year 1884; first contact with the earth's dark shadow at 10h. 42m., the middle of the eclipse at 12h. 8m., magnitude 0·59, and last contact at 13h. 34m. On October 4, 1884, there will be a total eclipse of the moon, the middle near 10 P.M., and the passage through the shadow nearly central.

THE AUGUST METEORS.—The earth will arrive at the descending node of the orbit of the comet 1862 III., in the track of which the meteors of the August period are found to move, soon after noon on Saturday next; the comet itself has now receded from the sun to a distance nearly equal to the mean distance of Neptune, to return to these parts of the system probably between 1980 and and 1985. Moonlight interferes this year with observation of the smaller meteors August 9-11, during a part of the night.

TEMPEL'S COMET.—The following places of this comet are deduced from M. Schulhof's elements, with the time of perihelion passage, corrected by the early observations at Strasburg by Prof. Winnecke:—

12h. G.M.T.	Right Ascension.	North Polar Distance.	Log. Distance from Earth.	Intensity of Light.
	h. m. s.	° ′		
August 23	16 20 30	109 3	9·9018	0·86
,, 25	— 25 55	109 52		
,, 27	— 31 28	110 40	9·9079	0·84
,, 29	— 37 12	111 27		
,, 31	— 43 6	112 13	9·9144	0·82
September 2	— 49 10	112 58		
,, 4	16 55 24	113 42	9·9213	0·80
,, 6	17 1 48	114 24		
,, 8	— 8 22	115 5	9·9286	0·77
,, 10	— 15 5	115 44		
,, 12	— 21 58	116 22	9·9365	0·74
,, 14	— 29 0	116 58		
,, 16	17 36 11	117 33	9·9448	0·71

On September 10 the comet passes very near to the orbit of Mars, but the planet is far distant. The dimen-

sions and eccentricity of the orbit of the comet are now :—

Perihelion distance ...	1·3393	Semi-axis major ...	2·9956
Aphelion ,, ...	4·6518	,, minor ...	2·4961

Eccentricity ... 0·55289

The interval between the perihelion passages in 1873 and 1878 is 1899·78 days.

BIOLOGICAL NOTES

THE PRIMARY GERM-LAYERS AND THE ORIGIN OF THE MALE AND FEMALE REPRODUCTIVE ELEMENTS.—Prof. Edouard Van Beneden, of Liége, three years ago observed that in the marine hydroid polyp Hydractinia the cells forming the testis and giving rise to spermatozoa, were derived from an ingrowth of the outer of the two primary cell-layers which form the foundation of all higher animal bodies, whilst the ova, he found, were simply cells of the inner primitive layer. This complementary function of the ectoderm and endoderm in Hydractinia led him to frame the hypothesis that throughout the animal kingdom the outer cell-layer is male in function, and the inner cell-layer female. On reviewing the facts known as to the derivation of the sexual cell-elements in various groups of animals, he was able to show a considerable amount of evidence in favour of the view that the testis is always ectodermal and the ovary always endodermal. Though accurate observations in this matter are excessively difficult, and definite knowledge as to the facts, in nearly all cases, is still wanting, yet Prof. Van Beneden's hypothesis was plausible and worthy of full consideration. It has been adopted by Gegenbaur in the last edition of his "Grundriss." The hydroid polyps consisting, as they do for the most part, of the two primary cell-layers in a very slightly differentiated condition, present the most ready field for the further testing of Van Beneden's hypothesis. The observations of Kleinenberg on Hydra were opposed to it. According to these *both* the sperm-cells and the egg-cells of Hydra develop from the ectoderm. Mr. J. Ciamician, of Vienna, has made a special study of this question in certain genera of hydroids (*Zeitsch. wiss. Zoologie*, 1878, part 4), and has published careful drawings in support of his statements. In *Tubularia mesembryanthemum*, assuming the accuracy of Mr. Ciamician's drawings, both female and male reproductive cells develop from a hollow in-growth of the ectoderm (the gonophors of the two sexes being distinct), which at first depresses the endoderm, but is afterwards itself flattened out by the up-growth of the endodermal layer of the spadix. In *Eudendrium ramosum* the ova develop from cells of the ectoderm, and the sperm-cells from cells of the endoderm, precisely the reverse of the relations detected by Van Beneden in Hydractinia. It seems hardly possible to interpret Mr. Ciamician's drawings of Eudendrium in any other sense than that which he himself adopts; the cell-layers at all stages are as clear in this species as they possibly can be. In the female gonophors of Hydractinia, Van Beneden saw an in-pushing of ectoderm at the apex developed in the same place as the in-pushing at the apex of the male gonophor, from which the sperm-cells developed. Van Beneden interpreted the rudimentary in-pushing in the female gonophor as a survival of a primitive hermaphrodite condition of the gonophors. Ciamician considers, on the contrary, that this ectodermal in-pushing is only the commencement of the formation of a medusa (in fact, the space between umbrella-margin and manubrium), which, instead of being completed, subsides into the condition of a medusoid gonophor. Hence, in place of a constant law of ectoderm being male and endoderm being female, we have in the three genera Tubularia, Hydractinia, and Eudendrium, the following variations respectively :—1, ectoderm male and female; 2, ectoderm male, endoderm female; 3, ectoderm female, endoderm male. The only possible generalisation from these facts is that of Ciamician, viz., that primitively the sexual functions are not assigned exclusively to cells of either layer: ectoderm may produce both male and female elements, and so may endoderm. With increased development and specialisation of structure, the production of reproductive elements would become limited to particular tracts of cells, and these would be necessarily *either* exclusively endoderm-cells or exclusively ectoderm-cells, but might be either one or the other indifferently even in closely-allied genera; and might be the same or complementary for the ovary and testis respectively. Nevertheless it must be admitted that though such indefiniteness in the relation of the sexual glands to the primitive cell-layers might be expected in Cœlentera where the differentiation of the two layers is at its commencement (both layers, for instance, developing nematocysts), yet in the higher groups of the animal kingdom we should be justified in looking for absolute constancy in the derivation of ovary and testis respectively from one or other (the same or diverse) of the two cell-layers—and we have not ground for supposing that this derivation would be the same in each of the great phyla until we can show that it is more constant in the Vermes than in the Cœlentera. E. R. L.

THE TOILET HABITS OF ANTS.—The Rev. H. C. McCook, of Philadelphia, eulogises the neatness of the agricultural ant, as observed in confinement at any rate. The most minute particles of dirt are carefully removed, and the whole body is frequently and thoroughly cleansed, especially after eating and sleeping. They assist each other in the general cleansing, and the attitude of the ant under operation is one of intense satisfaction, like that of a family dog being scratched, a perfect picture of muscular surrender and ease. Mr. McCook has seen an ant kneel down before another, and thrust forward the head under the face of the other, and lie motionless, expressing quite plainly the desire to be cleansed; the other ant understood this, and went to work. Sometimes this is combined with acrobatic feats, in which these ants excel, jumping about and clinging to blades of grass in a remarkable fashion. Sometimes the cleansing ant hangs downward from the grass, and to her the ant operated upon clings, reaching over and up with great agility to submit to her friend's offices. Evidently moisture from the mouth is used for washing. Mr. McCook has observed most minutely the whole of these processes, which are recorded in the Philadelphia Academy's *Proceedings* for this year. He suggests that with ants as with the human kind an artificial condition induces greater attention to personal appearance.

THE MODE OF RECOGNITION AMONG ANTS.—The combats and communications of ants are among the most interesting and mysterious phenomena. The Rev. H. C. McCook has given an account to the Academy of Natural Sciences at Philadelphia of some experiments he has made to determine what is the mode of recognition among ants. He has studied the pavement ants (*Tetramorium cæspitum*), which he has observed engaged in continued combat for over a fortnight, the warriors being only the workers or neuters. There is no distinguishable difference between the ants of the fighting parties, yet they recognise each other infallibly as friend or foe. They challenge all comers with their antennæ; if they are friends, they pass on; if foes, they straightway interlock and "fall to." Sometimes many ants are congregated against one, which is being torn limb from limb. Mr. McCook surmised that recognition was based upon a certain odour emitted by the respective factions. He found that if they were enveloped in an odour of eau-de-Cologne, while not at all deprived of activity, all became harmonious; those who were previously engaged in

battle unclasped one another, and they went on for several days amicably feeding, burrowing, and building. The same experiment was tried on the carpenter ants, which behead their enemies; their hostile proceedings were not stopped by eau-de-Cologne.

THE SNARE OF THE BASILICA SPIDER.—Science is under obligations to Mr. McCook of Philadelphia, for his study of the marvellous constructions of the Basilica spider (genus *Epeira*), near the Colorado River, Texas. It was first found about two feet from the ground upon a bush. The general form is pyramidal, the upper part of it a mass of straight lines knotted and looped, and crossing in all directions. Within this is suspended an open silk dome, of a vast number of radii crossed by regular concentrics. The dome was suspended from the upper erection so as to be perfectly steadied and kept in form. Beneath the dome was a light sheet of irregular cobweb. The spider itself is very beautifully coloured. This form appears to be a capital specimen of transition between the orb-weavers and the line-weavers. It has the characteristics of the line-weavers, namely, right lines and sheet-web in exact detail, and dome-shaped web in outline; it also has the geometric web of the orb-weavers, or radiating lines regularly crossed by concentrics. An allied species (*Epeira globosa*) is an orb-weaver, adding to the simple orb an open but distinct tube reaching almost to the centre of the web, with a free ray running along the floor of the tube, kept taut by the fore feet of the spider. An insect struggling in the web communicates the motion directly to the spider, which rushes along the covered gangway to its prey. Sometimes the gangway is imperfect, or even wholly omitted. The orb in the basilica spider appears to be the chief means of capture, the dome the dwelling-place, and the upper pyramid a suspension for this, and a protection against enemies.

SEXUAL CONDITIONS IN THE RED MAPLE.—It is commonly stated that maples bear hermaphrodite, male, and female flowers, but Mr. Thomas Meehan, of Philadelphia, asserts that the red maple is, according to his observations, really diœcious, having only flowers of one sex on the same tree. But the male and female flowers are similar in outward appearance at first opening, except that the small pistil is not developed in the male flowers. The female flowers have anthers of full size, and are supposed to be of both sexes, but the fact is that the anthers do not develop after the flower has opened, and shed no pollen. This is a very remarkable survival from a condition when the flowers were perfect. It is not uncommon to find trees, originally female, sending forth male branches, but Mr. Meehan has not found male trees produce female branches. The male flowers were found fragrant, the female not so.

GEOGRAPHICAL NOTES

UNDER the title of "Naturalists in the North West," a Sydney paper has recently published some interesting articles, the last of which relates to Mr. Miclucho-Maclay's account of the manners and customs of what he calls the Papuans of the Maclay coast. Their food consists mainly of vegetable products, but they have also some animal food, though it is somewhat scarce. Many of their domestic implements are of a very primitive nature; a flat splint of kangaroo bone forms a knife, of which a large kind is made from a smooth shell; axes are made sometimes of agate, and a few large ones, 3 inches wide, are kept as public property in each village. The dress of these natives is the *mal*, a piece of cloth prepared like the tapas of the Polynesians, from the bark of trees. The men all carry the *jambi* and the *gun*, to supply the want of pockets, the former being a bag suspended from the neck, and containing tobacco, &c., and the latter one woven of different coloured threads, and ornamented with shells. The *gun* is slung over the left shoulder, and contains the box of lime, betel-nut, knives, bamboo boxes of red and black dyes, &c. The natives also wear bracelets of bark or grass above the elbows, into which the *dougan* is thrust, and implements or weapons are also placed in the bangles on their legs. Wild boar's tusks are highly prized as manly ornaments to be worn on the chest, and ear-rings of tortoise-shell, bamboo, stones, or flowers, are all considered the proper adornment of the men. The women do not decorate themselves to the same extent, but they have cords from the upper part of one ear passing over the forehead to the other, and also bunches of dogs' teeth hanging from the lobes of the ears; they carry two bags, in one of which they place provisions and in the other their young infants or some pet pigs or puppies. Their huts and villages are situated in groups round clearings in the forest, and the plantations are usually at some distance. They have three sorts of houses—for the single people, the families, and a common house, principally used by the bachelors. These habitations do not resemble the pile-dwellings of the Western Papuans, and are only slightly raised above the ground. In each cluster of huts is a gong, like a boat raised on trestles, which, when struck in the right place, emits so great a volume of sound that it can be heard at a distance of six miles. It may be mentioned that these people have no means of obtaining fire, and frequently have to go to the hill tribes, who are acquainted with a cumbersome mode of friction by which they obtain a light.

GREAT exertions are being made by the Marquis de Croizier, and others, to ensure the success of the coming International Congress of Commercial Geography, which will be opened at Paris on September 23, under the presidency of M. Meurand, of the French Foreign Office. Numerous foreign societies have been invited to send representatives to the Congress, and we believe that the Royal Geographical Society will be represented by some members of their Council. The programme of the Congress is an extensive one, the numerous subjects proposed for discussion being arranged under the following five heads: Explorations et Voies Commerciales; Produits Naturels et Manufacturés; Emigration et Colonisation; Enseignement; and Questions Générales. A detailed programme and a *résumé* of the proceedings of the Congress will be published each day and forwarded to all the members. The meeting will be brought to a close on September 28.

AT a recent meeting of delegates of the German African Society at Berlin, it was resolved to grant the sum of 10,000 marks (500*l.*) to the International Association for the Exploration of Africa, and also to support Dr. Buchner, who is about to start for a tour through the districts lying south of the Congo River. The reports recently received from Herr Schütte, the engineer of the society, who is now at the Congo, continue to be favourable, and are accompanied by excellent maps of the districts he visits.

DR. OTTO FINSCH, the Director of the Natural History Museum of Bremen, will start for a scientific expedition to Australia at the end of this year; he is sent out by the Royal Academy of Sciences of Berlin, who will defray his expenses from their Humboldt fund.

THE ELASMOTHERIUM

AMONG the extinct animals of the diluvial age, few have left such scanty remains as the elasmotherium. At the beginning of the present century Fischer von Weldheim, when examining the palæontological collections of the University of Moscow, came across the half of the under-jawbone of an unknown animal, to which he assigned a place between the rhinoceros and elephant. The name elasmotherium was given to the new species,

on account of the peculiar appearance of the teeth, which seemed to consist of plates of enamel longitudinally folded. Later scattered teeth of this animal were found in Hungary, in Sicily, and in various Russian provinces. A few years since a complete under-jawbone was discovered at Petrowski; a fragment of the back part of a skull in the Museum of the Jardin des Plantes, at Paris, which was discovered on the banks of the Rhine in the last century, has likewise lately been identified as

FIG. 1.—Side view of the skull of the Elasmotherium

belonging to the elasmotherium. These remains were altogether too limited, to offer the zoologist any satisfactory clue to the general character of this animal. While the form and size of the jaw showed a strong resemblance to that of the rhinoceros, a close relationship was forbidden by the peculiar characteristics of the teeth.

Interesting as were the questions arising with regard to the nature and habits of this extinct resident of Europe, they have hitherto remained unanswered, until a fortunate discovery at the beginning of the present year, placed the zoologist in possession of a well-preserved skull of the elasmotherium. This object, certainly the most valuable of late palæontological discoveries, was found attached to the net of some fishermen in the river Volga, not far from its mouth, a district which has furnished many valuable remains of the extinct fauna of Russia. The St. Petersburg Academy of Sciences has become the fortunate recipient of the newly-found treasure, and to one of its members, Dr. Alexander Brandt, the scientific world owes the first complete summary of the deductions drawn from the study of this skull, as well as its detailed description. Besides his communication on the subject to the Academy, he has published a longer article in the Russian periodical *Niwa*, and translated it likewise into German.

The skull (Fig. 1) itself has the following dimensions. Length 33 inches, height, including the under-jaw, 21½ inches, breadth 16½ inches. Its most striking feature is an enormous bony protuberance on the brow. This is hemispherical in shape, possessing a circumference of over 3 feet, and projecting forward about 5 inches, and is hollow, forming a portion of the frontal cavity. Unusual developments of this cavity are noticeable in the skull of the ordinary cow, and more especially in those of the elephant and rhinoceros. As in the case of the latter animal, the protuberance of the skull of the elasmotherium presents a rough, uneven surface, traversed by deep furrows once occupied by blood vessels. The whole analogy with the rhinoceros points with the greatest certainty to the previous existence of a horn, which, to judge from the size of the blood-vessels once encircling the base, must have possessed enormous dimensions, and easily exceeded the length of the skull itself. The presence of a similar, rough protuberance of much smaller dimensions lower down towards the nostrils, would incline to the supposition that a second smaller horn was likewise present on the elasmotherium.

The front view of the skull bears a general resemblance to that of a horse or a ruminating animal. The rear portion of the skull, however, shows the relationship with the rhinoceros, and this relationship, at least, to the extinct rhinoceros, is still more strongly evidenced by the bony partition dividing the nasal cavity, a most peculiar and characteristic anatomical formation; for with the exception of these two animals, all other mammals known to us possess simply a cartilaginous division in this cavity. The structure of the teeth (Fig. 2) presents, on the contrary, no points of similarity with that of the rhinoceros. They are composed of winding folds of plates of enamel, extending the whole length of the tooth, and presenting, on the upper surface, an odd foliated appearance.

To judge from the skull in question the elasmotherium was most closely allied to the rhinoceros family, standing between it and the horse. Its proportions surpassed, however, those of any of its congeners, thus far known, existing or extinct. The proportions of the skull would point to a length of body ranging between 14 and 16 feet. With regard to the form of the body and limbs, nothing definite can be said. The nose was much narrower than that of the rhinoceros, while the eyes were larger, and the powers of vision of the elasmotherium, therefore, probably greater than those of the rhinoceros. Analogy with the contemporary rhinoceros and mammoth of

FIG. 2.—Grinding surface of tooth (natural size).

Siberia would warrant the supposition of the presence of a shaggy coat of hair.

The absolute, as well as the comparative size of the cranial cavity would assign to the elasmotherium a low degree of intelligence. Dr. Brandt pictures it as an

enormous animal, of great strength, but clumsy, awkward, and slow in its movements. It wallowed in the mud, lazily chewed its food of grass and tender twigs, and stretched itself to rest among the reeds or grass on the river's edge. From this apathetic condition it would be roused only by the attack of a rival, of a mammoth, of a rhinoceros, or of some one of the great carnivorous animals of that distant epoch. It would then rush enraged on its adversary, and endeavour to lay it low with its formidable horn.

The discoveries of remains of the elasmotherium show that it once wandered over the greater portion of Europe, from the Ural to the Rhine, and as far south as Sicily. It is also highly probable that later palæontological discoveries will show its existence in Asia, in company with the other large mammals, whose remains have been so well preserved in Siberia.

It was also in all probability contemporary with the men of the stone age, its remains occurring in the same deposits, in which the anthropologist finds the flints, collections of bones, and other evidences of prehistoric man. From their weapons the elasmotherium had probably little to fear.

In connection with this interesting discovery Dr. Brandt recounts a tradition of a tribe of Tartars in South Siberia, which describes the death of an enormous black ox. It possessed, however, but a single horn, and that of such size that it could be transported on sledges only. Possibly a reference to the elasmotherium.

UNDERGROUND MONSTERS

In a former number (vol. xvii. p. 325) we gave some account of a curious underground monster, the Minhocao, supposed to exist in Brazil. Dr. Spencer Baird, of the Smithsonian Institution, sends us an interesting document, which shows that the belief in such a monster is not confined to Brazil, but is shared in by the people of Nicaragua. In the *Gaceta de Nicaragua* for March 10, 1866, is a long letter signed "Paulino Montenegro," containing a circumstantial account of an object possessing very much the same attributes as the Minhocao. The letter is dated Jinotega, Nicaragua, February 21, 1866. The writer states that he went to Concordia on private business, when he heard on the 17th of a serpent having taken up its abode at a place called La Cuchilla, within the jurisdiction of the village. Along with some friends, M. Montenegro set out on the 18th to examine into the foundation of the report. A tradition concerning such a monster has existed from "time immemorial." After having travelled on that day about two leagues (1 league = 2·6 English miles) north-east from the village, they reached the spot where the inhabitants of the neighbourhood had traced signs and tracks, which, M. Montenegro states, positively prove the existence of such an animal.

The most detailed accounts stated that here, some five years before, a sort of platform of about fifty varas diameter had been formed at the foot of a large rock cropping out from a hillside. One of the neighbours had established there an orchard, though no one had been able to account for this new formation. Three years before, however, people began to observe that this little piece of level ground was gradually deepening, and that in the month of November the base of the rock adjoining it became exposed and worn from some agency, notwithstanding that there was not sufficient water to cause the phenomenon. At the same time mighty trees (*robles*[1]) were observed to become uprooted and to fall in great disorder, while immense rocks were moved and shifted their foundations so much, that in the following month of December, during one night, the road from Chichiguas and Cuchilla to San Rafael del Norte was destroyed by a multitude of cracks and clefts, which had suddenly opened. At that time the ground was observed to be undermined, falling in at intervals. These occurrences were observed some three days before M. Montenegro and his friends visited the place, which they saw all to be in accordance with the statements. Immediately on examining the locality for themselves they came to the conclusion that there were signs not of one but of two animals, probably of the shape of huge fishes.

In commencing their work these animals seemed to pursue a kind of an upheaving movement. As the bottom of their hiding-place was loose, shifting ground, the surface of this was seen to give way, while trees were shaken out and came down crashing. The noise of this seemed to scare the animals away. One of them—believed to have been the male on account of its larger size and greater strength—took to the left in descending, but always in a parallel direction with and along the slope of another hill, which here terminated. As it broke through the banks of a ravine, which measured about twenty varas in width and nine feet in depth at its greatest opening, he passed with his head underground. The thrown-up soil showed the tracks of the head, which left its marks both in the soil and on the roots of the trees, which were broken, the broken pieces being four inches thick. The main part of the body, which certainly must have passed here uncovered, left its traces at the bottom of the ravine. Passing out from this the animal entered upon ground more level and friable, which it went through at a depth of five quarters (1·25 varas), forming a furrow and leaving behind a ridge more than one vara high. Following the ravine for a distance of about sixty varas it encountered two deep ditches, when it turned and traced its way back, and, approaching the aforesaid ravine, took to the bed of a pond and disappeared perpendicularly.

The other animal, which left behind a smaller track, and therefore was believed to have been the female, went at once to the right, to the outlet of the pond of water before referred to, leaving behind it everywhere the same marks as the other. When it reached the two deep ditches it turned back also, and undoubtedly encountered its companion afterwards.

The whole ground had become irregularly disturbed and broken up, and the power of these animals is shown by their being able not only to throw up huge masses of soil but even to move rocks weighing more than thirty quintals.

The animals seem to be covered with a skin clad with scales or plates, the markings of which, imprinted on the soft clay or loam, bear much resemblance to those of the garrobo[1] in the mud. It appears that the shape of these animals must be like that of the guapote.[2] The length of the body is at least twelve varas, the height three, and its thickness 1·5 varas.

A tradition about such an animal as this has been kept up unaltered, without contradiction, for more than a hundred years. It is described in general as a large snake, and called "sierpe," on account of its extraordinary size, and living in chaquites.[3] One is said to have been once killed by lightning the moment it had left its hiding-place in the river "Sebaco viejo."

[1] "Roble," in Spanish, means an oak. The same name is found through various parts of Spanish America, applied to trees belonging to very different botanical families, having no natural affinities among each other, and also none to the "Cupuliferæ." On the River Atralo, in New Granada, South America, a huge tree, a species of *Tecoma*, is called "roble." The name "roble," no doubt, is given to these different forms merely on account of some external resemblance to an original Spanish species of oak.

[1] [2] "Garrobo" and "guapote" are names of which the exact application cannot be ascertained.

[3] "Chaquites" seems to be an Indo-Hispanic expression and a provincialism; probably pools or ponds is meant in the present case.

TWO AUSTRALIAN GEOLOGISTS

Australia has recently lost two of its most eminent geologists, the Rev. W. B. Clarke and Mr. Richard Daintree. The death of Mr. Clarke we noted some weeks

ago, and now by the kindness of a correspondent we are able to give a few details as to his career.

The Rev. W. B. Clarke was born on June 2, 1798, at East Bergholt, in Suffolk. In October, 1817, he went to Cambridge and entered into residence at Jesus College. In January, 1821, he took his B.A. degree, and in July, 1824, he was made M.A. and a member of the Senate. From May, 1821, until November, 1824, he officiated as curate of Ramsholt, Nedging, Whatfield, Chellesworth, and Brantham; after this he became curate for a time in his native parish. The rector seems to have had a proper appreciation of his talents, for he not only allowed but enjoined him to travel during a portion of each year, a privilege of which Mr. Clarke availed himself in order to pursue and complete the geological and mineralogical studies that he had commenced at the University under the teaching of Prof. Sedgwick and Dr. Clarke, the celebrated traveller in the Holy Land. During this period he made some fifteen distinct journeys of exploration either on the Continent or in different parts of his native land, enlarging his experience and acquiring fresh stores of information. In 1823 he was presented by Lord de Manley to a small vicarage in the county of Dorset, with a written promise of the succession to a desirable rectory in Gloucestershire. Having, however, rheumatic affection, and seeing no immediate prospect of succeeding to the Gloucestershire living, he determined to take a voyage to Australia, and arrived in Sydney in the year 1839. He appears to have found in Australia a fitting field, both for his labours as a clergyman and for the prosecution of his favourite studies in geology and mineralogy, and he at once applied himself to both. He had been considerably influenced in deciding to make Australia his home by correspondence he had had with the late Sir Thomas Mitchell, formerly Surveyor-General of the colony, and with the late Bishop Broughton, who had been his fellow-undergraduate at Cambridge. The first charge to which he was appointed was that of King's School, Parramatta, a position which he continued to fill until the beginning of the year 1841, after which he retired from the school, and attended only to his clerical duties. In 1844 he took charge of the parish of Willoughby, North Shore, with which he remained connected till 1870.

Mr. Clarke filled many positions of honour and distinction in connection with his own communion, and with learned and scientific bodies in various parts of the world. He was Fellow of St. Paul's College, vice-president of the Royal Society of New South Wales, trustee of the Australian Museum, trustee of the Public Free Library, Fellow of the Geological Society of England since the year 1826, member of the Geological Society of France, member of the Royal Geological Institute of Austria, member of the Royal Geological Society of London, &c., &c. In the department of science to which he had more particularly devoted his attention, he was regarded as an authority by all geologists. Perhaps his largest and best-known work is that entitled "The Southern Gold-fields," which contains an exhaustive description of the auriferous deposits throughout Australia. This work was written in consequence of Mr. Clarke having been commissioned by the Government to visit and report upon the principal gold-producing localities in the colony. A number of his papers were at different times read before the Royal Society of New South Wales, and are preserved among its records. They are almost entirely confined to subjects relating to geology, mineralogy, and meteorology.

Some two or three years ago Mr. Clarke was elected a member of the Royal Society of England—an honour which has been so rarely conferred upon colonial *savans* that Mr. Clarke valued it perhaps more than all the other distinctions he had won, especially as the honour was conferred upon him by the unanimous and spontaneous action of the Society. Mr. Clarke died on June 16.

The announcement of the death of Mr. R. Daintree, C.M.G., F.G.S., will be read with deep regret alike in this country and the Australian Colonies, more especially Victoria and Queensland. Next perhaps to that of Mr. Clarke, his name has been more intimately associated with geological science at the Antipodes than that of any other observer, more particularly in connection with the former province.

On his first arrival in Victoria Mr. Daintree became connected with Mr. A R. C. Selwyn, F.R.S. (now Director of the Geological Survey of Canada), in the geological survey of that colony, and did good work in the exploration of the Bass River, the survey of the Cape Patterson Coal-field, and other difficult explorations. He was also engaged in the survey of a large tract of country to the south-west of Melbourne, around the now flourishing town of Geelong, comprising the Barrabool Hills, the Anakil, and other minor ranges, and to the north the districts of Ballan and Bacchus Marsh. An accomplished photographer, his knowledge of this science was turned to good account in the preparation of a large number of photographs illustrative of the general geology of Victoria and Queensland, and more especially of the physical structure of the gold fields, and the methods in operation for the mining and extraction of gold. The formation and mode of occurrence of the precious metal attracted a good deal of his attention, more especially with regard to its presence in rocks associated with dioritic dykes in Queensland.

Mr. Daintree's connection with the Geological Survey of Victoria commenced in 1854, and, with the exception of a short interruption in 1857-8, continued down to 1864. In that year he left Victoria for North Queensland, and settled there as a "squatter," continuing at the same time to interest himself in matters geological. In 1869 the Queensland government appointed him government geologist for the northern half of the colony —a choice amply justified by the remarkably good work he performed whilst acting in that capacity. Queensland owes to Richard Daintree no ordinary debt of gratitude for the important part he took in the development of her mineral resources, the discovery of several important gold fields having followed quickly upon his prognostications.

Daintree's geological map of Queensland will give some idea of the vast tracts of country traversed and reported on during the course of his residence in that province, and on which the geological boundaries of the various formations were laid down with great care and precision. Whilst on this subject we would call attention more particularly to the definite delineation of the boundaries of the great secondary formation of north-eastern Australia about which little, comparatively speaking, was known up to that time, except the occurrence of typical fossils at a few isolated localities. The great tertiary series, aptly designated by Daintree the "Desert Sandstone," was shown to have extended over the greater part of Australia at one time.

In 1871 Mr. Daintree was appointed Special Commissioner for Queensland to the International Exhibition of 1872, and organised the admirably-arranged Queensland annexe, which was, in that and succeeding exhibitions, so universally admired. An experienced and determined bushman, he had, during his Australian career, paid too little attention to the preservation of his health, and in all probability laid the seeds of the complaint which afterwards terminated fatally. Soon after his appointment in March, 1872, as Agent-General for the Queensland Colony in London, his health began to give way, and his condition caused much anxiety to his numerous friends. Notwithstanding his removal to a warmer climate during our winters, signs of pulmonary disease

rapidly manifested themselves. He died last month, at the early age of forty-seven years. By his death there has passed from amongst us a true, most unselfish, and large-hearted man, a true friend, and a most agreeable companion. He was an accomplished geologist, a close and accurate zoological observer, a thoroughly practical chemist, and a photographer of no mean order. It will be long ere the vacancy in Australian science will be filled.

THE BRITISH ASSOCIATION

TWENTY-ONE years have passed since the British Association met in Dublin. It was then under the presidency of Dr. Lloyd, the venerable, but still hale, Provost of Trinity College. On Wednesday next, as our readers are aware, the forty-eighth annual gathering of this congress of science once more meets in the metropolis of Ireland, the President-Elect again being an eminent mathematical physicist, Dr. Spottiswoode.

Notwithstanding the fact that Dublin is now as easy of access from London as Edinburgh, and as near in point of time, yet the average Englishman knows far more of Paris or Switzerland than he does of the sister-isle. We trust the forthcoming meeting in Dublin will help to remove much of the prejudice with which Ireland is regarded, prejudice which proceeds from ignorance. For instance, not long ago an eminent scientific Englishman having been asked to lecture in Dublin, seriously inquired whether it would be advisable to be armed with a revolver, exhibiting a fear less reasonable than that of the man who, on a visit to Christiania, took precautions against being attacked by bears. Dublin no longer deserves the second adjective in the epithet of "dear dirty Dublin," in fact, its well kept streets, its splendid buildings and squares, the activity of its commercial and intellectual life, delight and surprise the stranger. In point of situation it is, perhaps (at least next to Edinburgh, our Scotch friends will think), the most beautiful capital in the world, backed by the Dublin and Wicklow Mountains, flanked on one side by the Hill of Howth, and on the other by Bray Head, the Bay of Dublin, with its clear blue water, is even comparable in beauty to that of Naples, if corresponding atmospheric conditions be granted.

Unusual facilities have been offered by the railway and steam-boat companies for the conveyance of visitors to Dublin. To some of our readers it may be convenient if we summarise the ways of reaching Dublin from London. The quickest route is of course by the Irish day or night mail from Euston Square: for example, leaving London at 8.25 P.M., one is landed in Dublin before seven the next morning. The splendid and perfect arrangements of the mail steamers from Holyhead to Kingstown are too well known for us to describe them. Recently the London and North Western Company have built two magnificent steamers, which run during the day from Holyhead to Dublin, and *vice versâ*. The fare is less than by the mail, and the boats are quite as large and sumptuous as the mail-boats, though not quite so fast. To those who intend travelling second class (there is no third by the mail) we should recommend their selecting the North Western boats from Holyhead to North Wall, Dublin; second class passengers being allowed to use the first class saloon without extra charge. The night boat, which meets the 5 P.M. train from Euston, is not quite so fine as the day boat, but the visitor has the advantage of entering the Bay of Dublin by daylight, reaching North Wall about 7 A.M. At the present season of the year no alarm need be felt on the score of sea-sickness by those who travel in the mail-boats from Holyhead to Kingstown. The boats are so large and steady that even with a considerable wind little motion is felt; and the passage is very short, about four and a half hours being the average. Another route is *viâ* Liverpool to Dublin, these are good boats. Lastly, to those who prefer a long sea-trip and can spare the time, nothing is more pleasant than going from London to Dublin direct by steamer. So much for transit. As regards accommodation in Dublin, the Executive Committee have provided a very complete list of lodgings; and the hotels, we understand, have not raised their usual tariffs.

The arrangements of the meeting we have already announced. The sections will meet in Trinity College, the addresses will be delivered in the Exhibition Palace, and lectures will be given by Mr. Romanes and Prof. Dewar an August 16 and 19. On August 15 a *soirée* will be given by the Royal Dublin Society to the Association. This promises to be a very brilliant affair. The Department of Science and Art has allowed a liberal selection of objects from the South Kensington Museum and the Science Collection to be lent for the occasion. Electrotype reproductions of many of the most interesting relics exhibited in the Loan Collection of Scientific Apparatus will be shown at this *soirée*, together with other curiosities from South Kensington. Dr. Spottiswoode has also kindly lent one of his new leviathan condensers which, used in conjunction with an enormous induction coil lent by Mr. Horatio Yeates, will be sure to attract much attention during the evening, and further, the Stereoscopic Company have promised to exhibit the phonograph at this *soirée*. A *conversazione* will also be given by the Royal Irish Academy, when its unrivalled museum of Irish archæology and antiquities will be seen to advantage and with interest by the members of the Association.

No neighbourhood lends itself so easily to beautiful excursions as that around Dublin, and the excursion programme this year is most varied and complete. Here is the list for Saturday, August 17:—

High Park and Artane Reformatories, to be entertained at the Artane Reformatory; St. Doulough's Church, Malahide Castle, and antiquities of Swords, to be entertained by the Right Hon. Lord Talbot de Malahide; Bray Head, Kilruddery Demesne, Hollybrook, Charleville, the Dargle and the Scalp, to be entertained by the Right Hon the Earl of Meath; Maynooth R. C. College, Carton, Lord Annaly's and Phœnix Park, to be entertained by his Grace the Duke of Leinster; Howth and Ireland's Eye (walking excursion), to be entertained to afternoon tea by residents of Howth; Lucan and Leixlip, Valley of the Liffey, Woodlands and Phœnix Park, déjeuner will be provided by committee at Lucan; Irish Lights Board, Dublin Bay—steamer *Alexandra*, to be entertained on board the steamer by Irish Lights Board; London and North Western Railway—steamer *Rose*, to be entertained on board the steamer by Committee; Glencree Reformatory, Killakee Demesne, Waterfall, Dargle and Enniskerry, to be entertained at Glencree Reformatory by the Managers.

For Thursday, August 22 this is the list:—

Glendalough and Seven Churches, to be entertained at Newrath Bridge; Vartry Waterworks, déjeuner at Vartry Lodge; Vale of Avoca, déjeuner at Glenart Castle, given by the Earl of Carysfort, and at Skelton Abbey, by the Earl of Wicklow; Boyne, déjeuner at Drogheda; Cashel, déjeuner at Limerick Junction; Parsonstown, déjeuner at Birr Castle, given by the Right Hon. the Earl of Rosse; Powerscourt, déjeuner at Powerscourt Castle given by Viscount Powerscourt; Curragh Camp, déjeuner at Stand House, Curragh; Kilkenny, déjeuner at Kilkenny Castle, by the Most Noble the Marquis of Ormonde; and on Friday, August 23, an excursion is arranged to Belfast, luncheon being provided at Glanmore, Lisburne, by Messrs. Richardson and Sons, with dinner at Belfast.

Dublin is famous for its hospitalities, and, amid other festivities, the following have been arranged:—On the morning of Monday, the 19th, members will be enter-

tained at breakfast in the Zoological Gardens by the Royal Zoological Society, in the afternoon at a dinner by the College of Physicians, and in the evening at a *conversazione* by the Royal College of Surgeons. Their Graces the Duke and Duchess of Marlborough will also hold a reception in the Viceregal Lodge and entertain a number of distinguished visitors at dinner.

Several eminent visitors have already announced their intention of being present at the meeting, among others Messrs. Cornu, Chevalier, Brown-Sequard, Emile de Laveleye, Perier, Feil, Bertrand, Ranvier, Maas, Zirkel, Vogel, Salensky, Kanitz, Wittmael, Stricker, Cope, Sylvester, Draper, Sterry Hunt, H. M. Stanley, and Capt. Burnaby.

Through the unceasing labours of Dr. Ball the Royal Astronomer for Ireland, Dr. Norwood, and their co-secretaries, Dr. Sigerson and Mr. Goff, the meeting promises to be an unusually good one.

NOTES

MR. CHARLES DARWIN has been elected Corresponding Member of the Paris Academy of Sciences in the section of Zoology by 26 votes against 14. This success is all the more notable that Mr. Darwin obtained only 5 votes in a scrutiny which took place quite recently. Prof. Asa Gray has been elected a corresponding member in the Section of Botany in succession to the late Dr. Braun of Berlin.

AT the meeting of the French Association, of which M. E. Fremy will be president, M. Janssen will give a lecture on a question of physical astronomy, Prof. V. Trélat one on the Hospital, and Prof. Marey another on graphic researches relative to animated motors. Among the sectional papers promised are the following:—In the Mathematical Sciences, Signor V. Cerruti, of Rome, on the infinitely small movements of a solid body. In Physics and Chemistry, Prof. Crova on the solar heat; M. Ducretet on the liquefaction of gases; M. Janssen on new data obtained by photography on the constitution of the sun, and on the constitution of photographic spectra of short exposure; M. Montigny on the scintillation of the stars; M. Woeikoff on climatological researches. In Natural Science, Dr. Alix on myology of mammals; Dr. Baillon on the development of the ovular teguments; Dr. Blandet on geological periods before the secular variations; Prof. Chauveaux on the rate of propagation of excitations in the vaso-motor nerves; Prof. A. Gaudry on the evolution of primitive mammals; M. A. F. Nogues on method in geology, and on the climatology of geological times; Dr. Topinard on the notion of race in anthropology. Altogether there are about 250 papers already down to be read.

WE notice that the Bavarian Academy of Sciences at Munich at its last session elected to membership the famous French chemist Prof. Adolphe Wurtz, of Paris. Prof. Wurtz is at present engaged in a careful study of the more modern chemical laboratories of the German universities, preliminary to the completion of the plans for the new laboratory in connection with the École de Médecine at Paris. This structure will face on the new Boulevard de St. Germain, and its erection will require about five years. When completed it is expected that it will rank among the model laboratories of the world.

THE Berlin Academy of Sciences has elected to its membership the astronomer, Prof. Aubers, and the archæologist, Prof. Conze.

SOME improved forms of microphone and telephone are described in the August number of *Scribner's Monthly*. One form of telephone, as devised by Mr. Phelps, gives surprisingly good results. It contains two diaphragms, and in shape somewhat resembles a double crown. Twelve permanent magnets bent into a circular form are used in place of the single magnet employed in other magneto-telephones. Six of these on each side of the instrument have their like poles joined to one of the cores which carry the helices, and radiate from it in as many different directions. The opposite poles are joined to the periphery of the diaphragm on the corresponding side of the instrument, while the helices are so connected that the currents generated in them when the diaphragms are made to vibrate mutually strengthen each other and thus contribute to the effectiveness of the apparatus. Some idea of the performance of these improved instruments will be conveyed by mentioning the results obtained at a recent exhibtion of them in the Sunday-school room of Dr. Wells's church, Brooklyn. Mr. Edison's carbon transmitter was used for sending, and Mr. Phelp's crown telephone for receiving. The sound was also reinforced at the receiving end by the use of a large paper cone, whose smaller extremity was held to the mouthpiece of the instrument. The circuit extended from the residence of Dr. Wells, near the church, to the lecture-room. Speech from the telephone was distinctly heard in all parts of the room by an audience of about three hundred persons, while the singing of a vocal quartette, solo singing, and guitar playing, were transmitted with surprising clearness and loudness. It should be observed, moreover, that the performance in this case was very different from the so-called musical telephones by means of which only the pitch and rhythm of the notes are distinguished, the tone always resembling that of a penny trumpet. In this instance the quality of the tone, which is the real life of music, was exactly reproduced; this is one of the characteristics of the magneto-telephone—everything is faithfully reproduced. Dr. Wells addressed the audience from his parlours through the telephone, and not only was he clearly understood, but his voice was also instantly recognised.

THE observatory of the University of Jena, which occupies a romantic site in the garden where Schiller wrote his "Wallenstein," has been for three years unoccupied since the death of Prof. Schrön in 1875. By a recent appointment Prof. Abbe has been assigned to the chair of astronomy, and will commence active duties in the observatory.

THE seventeenth annual meeting of the Devonshire Association for the Advancement of Science, Literature, and Art, was held on July 30 and 31, and August 1, at Paignton. Mr. W. Froude, F.R.S., was the president-elect, but in consequence of the lamented death of his wife that gentleman was unable to discharge the duties of the office, and at the last moment Sir Samuel Baker, F.R.G.S., was chosen to fill the vacant place, and delivered an address upon the chief points of progress in the past half century. The list of papers was a very full one, thirty-four in all, including the reports of the various committees through whose action much of the work of the Association is now systematised. Thus there are committees at work upon the subjects of Devonshire meteorology, folk lore, celebrities, verbal provincialisms, Dartmoor, the Devon domesday, and for the collection of scientific memoranda of a miscellaneous character; and to these two others were added at Paignton, one to collect and to record facts relating to Devonshire barrows, and the other to perform a similar duty with regard to ancient and still existing manorial customs. Scientific papers predominated, and among these geological papers occupied the foremost place. Mr. Pengelly, F.R.S., contributed a fourth instalment of his collections of the literature of Kent's Cavern prior to the investigations of the British Association; a fifth set of "Notes on recent Notices of the Geology and Palæontology of Devon;" and papers on "The Geology of the North-Eastern Coasts of Paignton;" "Cetacean Remains found in Torbay;" and a second instalment of "Notes on Slips (*i.e.*, blunders of various writers) connected with Devon-

shire." Mr. W. A. E. Ussher, F.G.S. (Geological Survey), read papers on "The Geology of Paignton," and "The Mouth of the River Exe;" Mr. R. N. Worth, F.G.S., "On the Origin of the Ossiferous Deposits at Oreston;" Mr. A.R. Hunt, F.G.S., "Notes on Torbay," the Rev. W. Downes "On the Fossils of the Culm Measures about Holcombe Regis," while Mr. E. Parfitt contributed another important instalment to his fauna of Devon —a list of the *Lepidoptera*. There were several other papers of a more general character. Some of the papers gave rise to lively discussions, and incidental to one by Mr. Ussher, Mr. Champernowne, F.G.S., entered upon a brief exposition of his views of the Devonian question. The whole of the papers read will appear in the *Transactions*. The membership of the Society continues highly satisfactory, approaching 400.

AFTER a lapse of some twenty years the Oreston quarries have yielded another ossiferous fissure, the contents of which were removed under the direction of Mr. R. N. Worth, F.G.S., and will be deposited in the museum of the Plymouth Institution. The quantity of remains is not large, and they are almost wholly of *Bos* and *Cervus*, but the find is valuable inasmuch as it adds to the Oreston cave fauna the Aurochs (*Bison priscus*) and Great Irish Elk (*Megaceros*), and thus reduces the points of difference between the Kent's Hole fauna and that of Oreston. The relics of the Aurochs include a very fine horn core in an excellent state of preservation.

IN its last session the Municipal Council of Paris voted a sufficient sum to defray the expenses of a laboratory for the detection of adulterations in articles of food, a want the necessity of which has long been felt. At the same session 6,000 francs was appropriated for the purchase of tickets to the Exhibition, to be placed at the service of the teachers of the city.

THE Royal Archæological Institute commenced its annual meeting this year at Northampton on Tuesday last week. Lord Talbot de Malahide, president of the Society, presided, and congratulatory addresses were read from the municipality, the local clergy, and Architectural Society. Lord Malahide then vacated the chair in favour of the Ven. Lord Alwyne Compton, president of the Northampton meeting, who delivered an address. The week was devoted to visits to places of archæological and historical interest and to sectional meetings.

THE British Medical Association commenced its forty-sixth annual meeting at Bath on Tuesday, when it was calculated that upwards of 1,000 members were present. The proceedings commenced in the morning with Divine Service at the Abbey. During the afternoon some business meetings were held, and in the evening Dr. Falconer, of Bath, the president for the year, delivered his opening address.

M. LEVERRIER established at the Paris Observatory a daily journal which published not only the warnings of the meteorological service, but also all the astronomical news of general interest. The separation principle having prevailed, the *Bulletin International* is now entirely devoted to meteorological purposes, and the Observatory has no means at its disposal for conveying to the public the observations it receives, except by the channel of daily papers. It was only by chance that information as to Watson's discovery of an intra-Mercurial planet was obtained by the papers from Admiral Mouchez. The Admiral is preparing to establish at the Observatory a course of lectures on astronomical observations during the winter months. During summer the pupils will be admitted to practise with instruments belonging to the establishment. The pavilion in the Paris Observatory in which has been placed the transit instrument given by M. Bischofsheim, will be called Bischofsheim Pavilion. Admiral Mouchez has decided that the public shall be admitted twice a month to the Paris Observatory instead of once as usual. Letters requesting admission are to be directed to the Secretary of the Observatory.

ON Sunday next a monument will be inaugurated at Chamounix to Jacques Balmat, who was the first to ascend Mont Blanc. The *fête* is due to the co-operation of the Geological Society of France and the French Alpine Club. The programme is a very brilliant one, comprising an ascent of Buet and various rejoicings at Chamounix.

THE Helvetic Society of Natural Sciences meets at Berne on August 12, 13, and 14.

THE monuments to Alexander and Wilhelm von Humboldt, the former by Prof. Begas, the other by Herr Otto, will soon be erected one on each side of the entrance gate to the Berlin University. Both monuments are in marble and the figures are represented in a sitting position.

SENOR RAIMONDY, one of the first scientific authorities of Peru, has just published a new work on the minerals of Peru which is specially intended for the use of those who wish to examine more closely the rich and valuable collection of Peruvian minerals sent to the Paris Exhibition.

WE recently referred to Dr. Siemens' idea that the Falls of Niagara might be utilised to supply industrial wants. This idea seems likely to be realised, as we learn that a company has been formed in America to make use of the Falls to transmit to Buffalo, twenty-two miles distant, a constant supply of compressed air, which it is expected will be used as a substitute for steam in the principal establishments at Buffalo.

AN earthquake is reported from Jenbach (Tyrol); it occurred on July 19, at 10.32 A.M., and lasted for ten seconds.

M. ELISÉE RECLUS, the eminent geographer, who had been sentenced to transportation for the part taken in the communistic troubles, but had his sentence mitigated to exile, has, by a recent decree of the President of the French Republic, been authorised to return to Paris.

THE great Trocadéro lift is in full operation. The number of persons that can be elevated at once is fifty. In a single day 1,200 persons have used it. The time required for ascending is about four minutes for an altitude of fifty-three metres. The velocity is rather great at first, but gradually diminishes, and is very slow at the end. The distance run is about $\frac{1}{10}$th of the elevation reached by the captive balloon.

THE ascent of the Giffard captive balloon was stopped on July 31, owing to the wind-pressure suddenly increasing to eighteen pounds per square yard. No attempt was made during the two following days, but the wind having diminished it ascended again on August 3, at two o'clock. The air was so humid that the balloon seen from the earth appeared almost lost in clouds. Various interesting observations have been made.

WE have received a specimen sheet of a catalogue of books and papers on Electricity and Magnetism, compiled by the late Sir Francis Ronalds, F.R.S., which will shortly be published by the Society of Telegraph Engineers. This catalogue, which contains more than 12,000 entries, and will probably extend to over 600 pages, is believed to include every important work and almost every paper which has been published upon the subject of Electricity and Magnetism up to the date of its author's death in 1873. It also forms a valuable catalogue of scientific works generally. Sir Francis Ronalds devoted the greater part of his lifetime to its compilation and in the formation of the valuable library now in the possession of this society. It is proposed, should the number of subscribers be sufficient to cover the extra cost for printing, &c., to issue a separate librarian's edition,

printed on one side of the paper only, for the use of librarians. The price to subscribers of each copy in this form will be 20*s*., delivered post free in the United Kingdom, and plus the extra postage for abroad. The price of the catalogue in the ordinary form will be 16*s*. The importance of this enterprise, not only to science but to bibliography generally, need not be insisted on. Those interested should communicate with the Librarian of the Society, 4, Broad Sanctuary, Westminster, S.W.

A LARGE coal-field, we learn from the Sheffield *Daily Telegraph*, has just been opened out near Hemsworth, about seven miles from Barnsley. The thick or Barnsley seam of coal has been reached on the estate of Mr. Allott, at a depth of 635 yards from the surface. This proves that a well-known and valuable bed exists in what may be termed the largest unworked coalfield in the West Riding. The shaft is the deepest in South Yorkshire, and the field in which the seam is worked commences at its southern extremity close to the town of Nottingham, and extending through Derbyshire, proceeding along the margin of the limestone to Barnsley and the east of it and the Ashworth Rock. The great coal-field, which includes parts of Derbyshire, Yorkshire, and Notts, is the largest in England, and only 150 square miles less in area than that of South Wales, the extreme length being sixty-six miles. The southern boundary is new red sandstone, and the strata rise and cross out westward near Bradford and Leeds, and then turning to the east, disappear under the magnesium limestone. The thickness of the bed near Hemsworth is about eight feet, which may be considered as about the average in South Yorkshire, while at Shireoaks Colliery, near Worksop, it is little more than three feet. The new colliery will be able to raise, when fully opened out, more than 1,000 tons daily, so that there will be an addition to the coal-producing power of South Yorkshire of 400,000 tons a year.

THE possibility of keeping a manatee in a healthy state in an aquarium is fully proved by the good condition of that at Westminster. It arrived on June 20, and has increased in size and done well. The only other specimen brought alive to England lived at the Zoological Gardens from August 6 to September 7 only, in 1875. At Westminster the animal is in a glass tank above the level of the ground, and accessible on both sides, so that its movements, position in floating, &c., can be well seen.

THE *Times'* notice of Bank Holiday amusements speaks of the Nubian Camp at the Alexandra Palace as an educational entertainment. In this we quite agree, and hope that every success may attend such instructive exhibitions as this.

RESPECTING the tornado, by which Canton was visited on April 11, the Rev. John Chalmers writes to the London Missionary Society that after careful inquiry and personal observation, he concludes that the whirlwind did not extend much further than three miles, the average width of its path being about three hundred yards. But on the next two days there were several distinct whirlwinds of a similar character in the neighbourhood. Over the space above indicated the tornado seems to have equalled in force and destructive effect anything of the kind heard of in the West Indies.

IN our "Meteorological Notes," vol. xviii. p. 287, the name of Mr. Eliot, who is officiating for Mr. H. F. Blanford in India, during the absence of the latter, should have been quoted instead of that of Mr. Blanford, as the authority for the forecast of the monsoon referred to.

AN astronomical correspondent suggests that in Mr. Lockyer's Eclipse telegram last week the words "Corona probably photographed in Siam. Fluorescent eye-piece worked well," should read "Corona probably photographed; it seemed fluorescent. Eye-piece worked well." With respect to the place of "Vulcan" as observed by Watson, R.A. 8° 26′ should be R.A. 8h. 26m.

THE additions to the Zoological Society's Gardens during the past week include a Slow Loris (*Nycticebus tardigradus*) from Borneo, three Chinese Cranes (*Grus longirostris*) from China, presented by Mr. Theodore Hance; a Mexican Deer (*Cervus mexicanus*) from Mexico, presented by Mr. A. Scrutton; a Common Fox (*Canis vulpes*), European, presented by Mr. Athelston Riley; three Great Bustards (*Otis tarda*) from Spain, presented by Lord Lilford, F.Z.S.; a Tiger Bittern (*Tigrisoma brasilianea*) from South America, presented by Mr. Hammond Hawbyne; a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, presented by Mrs. A. A. Hole; a Passerine Owl (*Glaucidium passerinum*), a Bacha Eagle (*Spilornis bacha*) from Borneo, presented by Mr. J. S. Jameson; two Beisa Antelopes (*Oryx beisa*) from North-East Africa, a Brown Coati (*Nasua nasica*) from America, deposited; an Ocelot (*Felis pardalis*), a Black Vulture (*Cathartes atratus*) from America; two Chilian Sea Eagles (*Geranoaëtus melanoleucus*), a Brazilian Caracara (*Polyborus brasiliensis*) from South America, two Rufous Tinamous (*Rhynchotus rufescens*) from Brazil, nine Spotted Tinamous (*Nothura maculosa*) from Buenos Ayres, a Razor-Billed Curassow (*Mitua tuberosa*) from Guiana, purchased; an Axis Deer (*Cervus axis*), born in the Gardens.

THE PHONOGRAPH AND VOWEL-SOUNDS[1]

II.

IN our last communication we confined our attention to the letter *ō*. We will now turn to the letter *ū* (corresponding to *oo* in "food"). Fig. 2 shows a series of curves obtained for

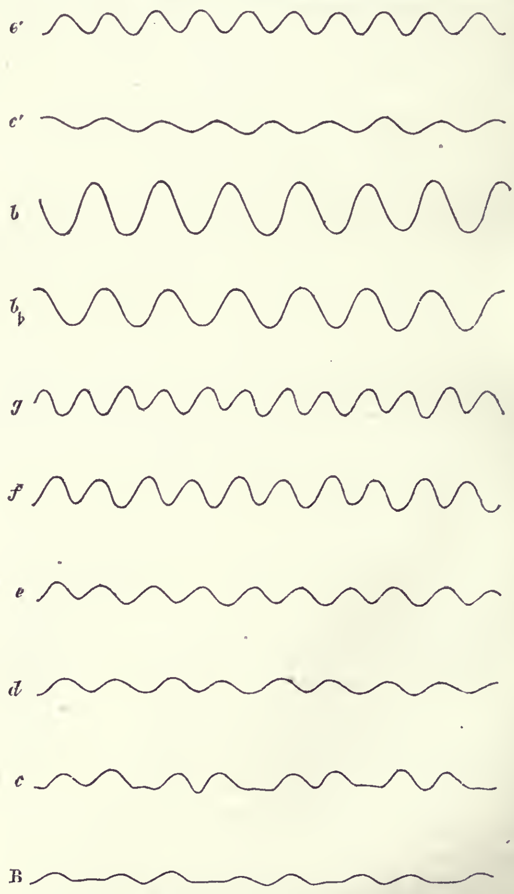


FIG. 2.—*Wave-forms of ū Sung by the same Voice at Various Pitches*

ū by the mechanical process already described. They are all

[1] Continued from p. 343.

sung by one voice: that numbered 5 in our previous communication.

Table V. gives the amplitudes of the first six harmonic partial tones for this series; and Table VI. gives the same constituents of another series of *ū*'s, sung by the voice formerly numbered 1.

Comparatively few curves have been transcribed for the sound *ū*, because the groups of constituents in this letter are much simpler than those in *ō*. Moreover, although the curves for only two voices have been analysed, we have by numerous examples satisfied ourselves that the selected examples represent with sufficient accuracy results produced by several other voices.

In examining Fig. 2 it must be borne in mind that the phonograph was turned in all cases at approximately the same speed, as accurately as this could be done by aid of a metronome. The length of the period in the curve corresponds, therefore, to the duration of the vibration which the voice produced on each note. On the upper path of the scale the wave-forms are almost exactly simple harmonic curves, but from *g* down to *d* the period is composed of two halves each closely resembling

TABLE V.—*Harmonic Constituents of ū Sung at Various Pitches by Voice No.* 5.

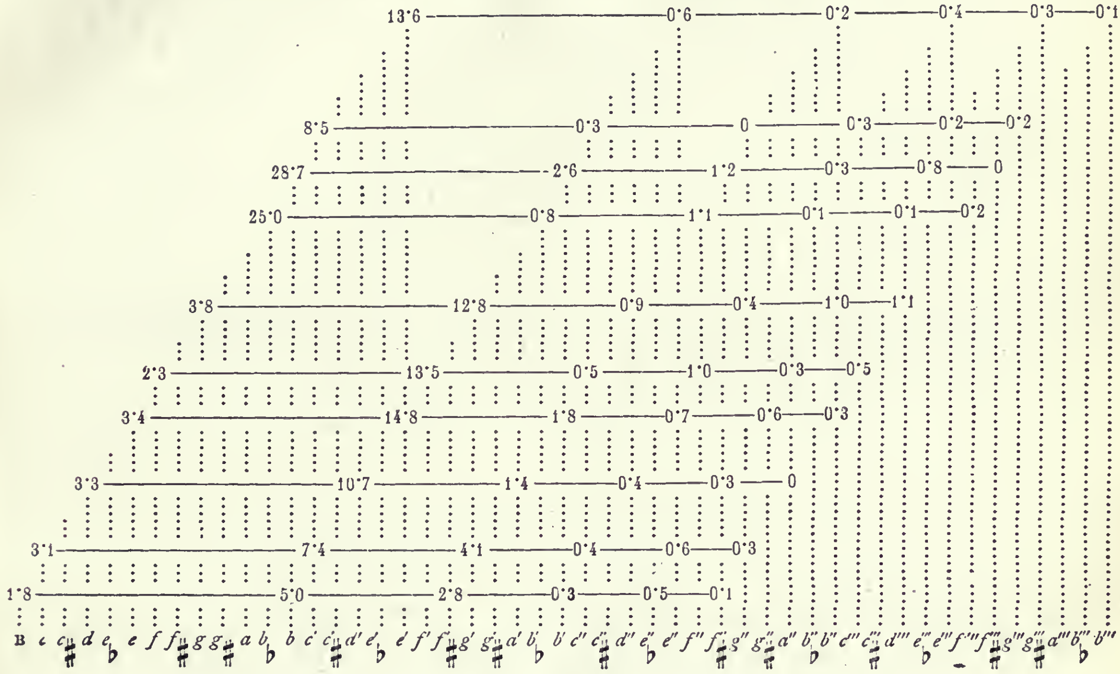

TABLE VI.—*Harmonic Constituents of ū Sung at Various Pitches by Voice No.* 1.

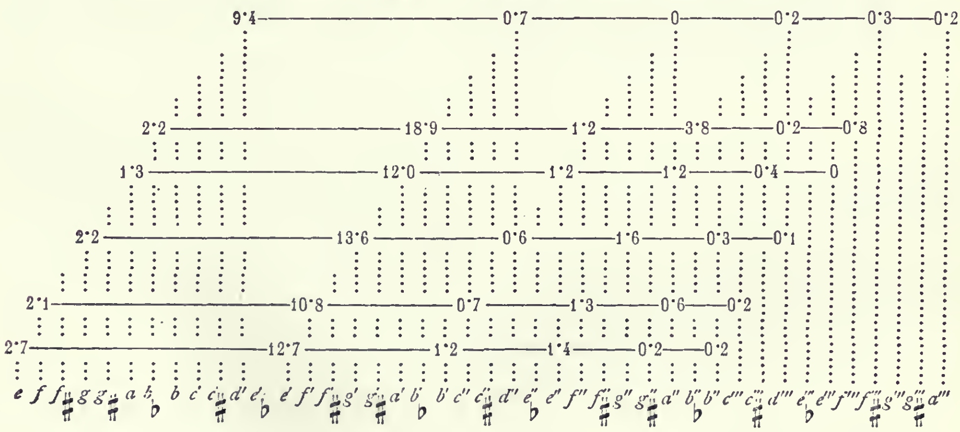

a simple harmonic curve, so that the form on *e*, for example, is not readily distinguished by eye from that on *e'*, an octave higher. Below *d* the curve breaks up into a somewhat irregular triplet.

We will call the curves for the notes above *b♭ simple ū* curves, and those from *g* downwards *duplex ū* curves. The analysis of the duplex curves shows that they consist of a very weak prime tone with an immensely strong second partial. The figures and tables might easily be extended above *e'*, but it is unnecessary to continue them, for the higher notes all give the same close approximation to the simple harmonic wave. We cannot say that we have obtained a good *ū* below *d* from any voice. The marks on the tinfoil were always feeble, and the sound as repeated by the phonograph was little more than an inarticulate groan. It will be observed that the note *a* is wanting in the tables and in the figure. It has been omitted because we had difficulty in getting a good *ū* back from the phonograph when the vowel was sung on this note. We have no doubt a good *ū* can be pronounced at this pitch, but we observed a constant tendency towards the *ō* character both in the curves and in the sound; that is to say, there was a tendency to give the two lowest partials instead of a simple prime, or a strong second and very weak prime. Moreover, the curves would vary in character

during the utterance, which was seldom, if ever, the case at other pitches, indeed, the constancy of the wave-forms produced by the voice over hundreds of periods has usually been very striking.

In order to maintain the *ū* quality throughout a series of *ū*'s, the change from the single to the duplex form had to be quite abrupt. To test the *ū* at this critical point *slurs* were executed by voice 5 both up and down; that is, attempts were made to

TABLE VII.—*Harmonic Constituents of ō Artificially Produced at Various Pitches.*

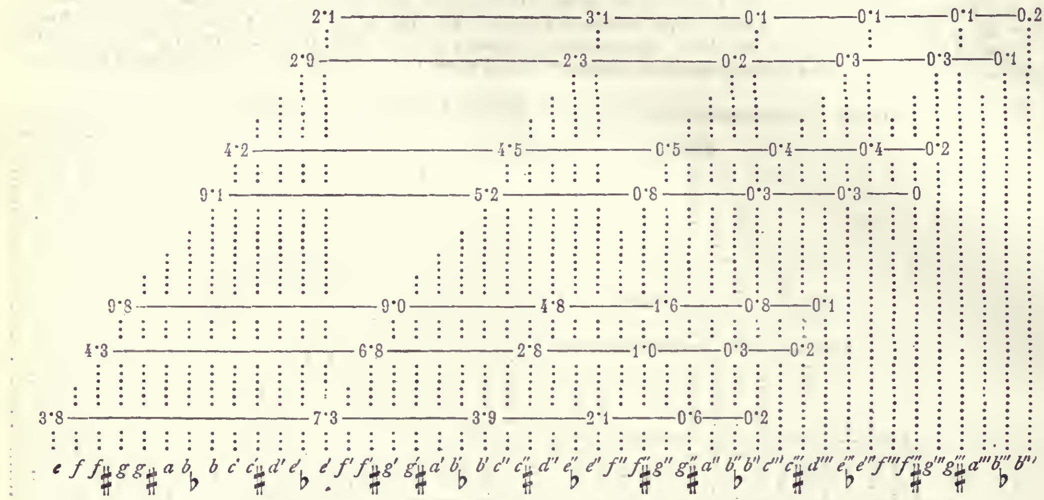

TABLE VIII.—*Harmonic Constituents of a° Sung at Various Pitches by Voice No.* 5.

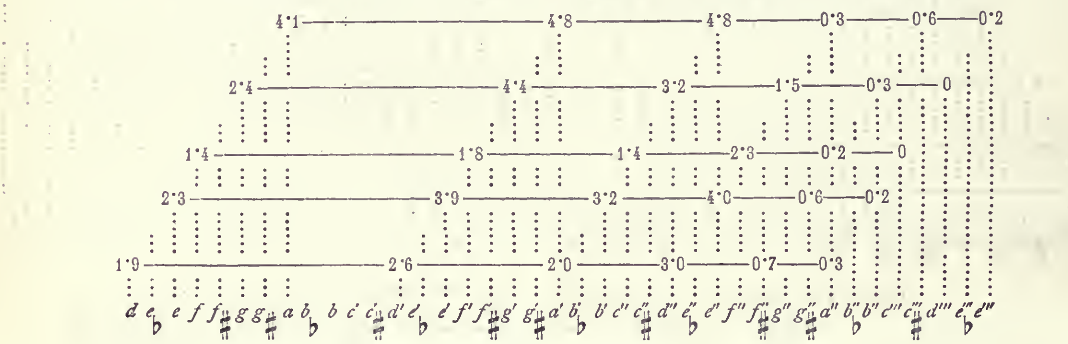

TABLE IX.—*Harmonic Constituents of ā Sung at Various Pitches by Voice No.* 5.

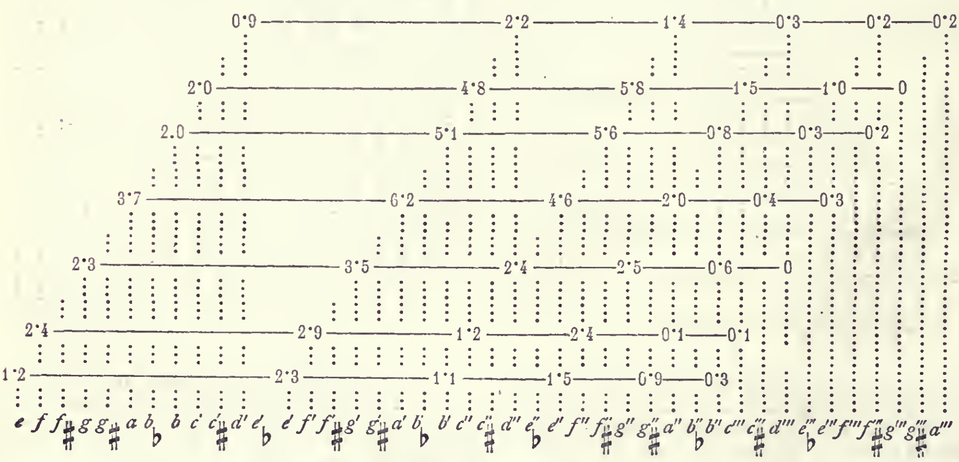

continue to say *ū*, and at the same time gradually raise and lower the pitch past *a*. At this pitch one of two things invariably happened. Either the curves became so like those for *ō* that they could not be distinguished from *ō* at the same pitch either by eye or ear, or they sunk to such an insignificant size as to indicate an interval of almost total silence.

One voice (No. 7) carried the simple harmonic form of *ū* down as low as *f*. This voice had a very limited range, and could not produce the duplex form at all. Moreover, the sound of the simple *ū*, while being spoken on *f* or *g*, was less vocal and more like a whistle than the duplex *ū* given by other voices.

One and the same voice, when singing on *a* or *b'♭*, would sometimes give the simple and sometimes the duplex form.

The following general propositions are, we think, established by these experiments:—

1. The generic character of *ū* from *d* upwards is given by the prominence of a single partial tone. Above *b♭* this partial is the prime. Below *a* with certain voices it is the octave of the prime.

2. The amplitude of the second partial is sometimes as much as nine times greater than that of the prime, but the sound will be recognised as *ū* when the second partial is only three or four times the size of the prime, provided the pitch of the prime is below *a*.

3. Below *d* the experiments do not warrant positive conclusions. The prominence of a single partial is less marked, and at the same time the vowel quality of the spoken sound is very poor.

4. The average pitch of the reinforced tones is generally lower than the average pitch of the group for *ō*.

5. We have not detected any single note having the marked characteristics for *ū* that were possessed by the note *b'♭* for *ō*.

6. There is a critical pitch in the neighbourhood of *a* or *b♭*, at which a sudden change takes place in the wave-forms given by certain voices in singing *ū*. Further experiments are desirable in this sound at this pitch. The critical pitch is not perfectly constant for a single voice.

As some doubt may not unnaturally be felt whether or not the singular change of character observed in *ū* at or near the note *a* may not have been due to some peculiarity of the instrument, we may repeat that, being fully aware of this danger, we tried the experiment repeatedly with changed mouth-pieces, changed vibrating discs, changed springs, and with different thicknesses of tin-foil, but invariably with the result that certain voices passed at this pitch from the simple to the duplex *ū*. It must not be forgotten, too, that one voice, using the same instrument, carried the simple *ū* as low as *f*.

7. This points to the fact that the change from simple to duplex *ū* is not made on account of the requirements of the ear, but on account of the difficulty in adjusting the mouth-cavity so as to continue the simple form on the lower notes. We have seen that, not only do different voices make the change at different pitches, but a single voice gives sometimes one and sometimes the other form at pitches near its critical point. We thus see that the simple and duplex forms overlap, and that in this case sounds of the same pitch, which differ by a whole octave in the pitch of their single prominent tone, are accepted by the ear as generically the same vowel.

The prominent tone in *ū* is found to lie in the region from *a* upwards, but we have not found any one sharply-defined pitch to be characteristic of *ū*.

With reference to the theory of characteristic tones in vowel-sounds we draw attention to the very great prominence of the tone *b'♭* (the characteristic tone of *ō*) when voice 1 sang *ū* or *b♭*. What may be termed the average pitch in *ū* is for notes near *d* and *e* lower than that in *ō*, owing to the absence of the third partial; but it is noteworthy that, as the voice runs up the scale, the constituents of *ū* are on an average higher than those of *ō* for *g*, and in the case of voice 1 even for *b♭*; this arises from the comparative smallness of the prime. When the simple form is reached the average pitch of the constituents is lower than that for *ō*. If, instead of looking at the average pitch, we look at the pitch of the highest and most prominent constituent, we find that this pitch is identical for *ū* and *ō* when these vowels are sung on *g* by voices 1 and 5, and when sung on *b♭* by voice 1.

Further light is thrown on the whole theory of vowels by experiments on the vowel *ō* as uttered by a mechanical contrivance made by Prof. Crum Brown and lent by him to us for investigation by help of the phonograph. It consisted of a bagpipe reed fitted to a tube leading into a gutta-percha resonance chamber which had such a form and such openings (tentatively arrived at) as caused it to speak a very good *ō* when the reed was blown. No one listening to this sound could doubt that the letter *ō* was being distinctly spoken. We held this apparatus to the phonograph, and the record obtained from it gave back a remarkably good *ō*, better indeed than the original, as the jarring noise of the reed was lost. When the pitch of the reed was changed, the same vowel continued to be given. The pitches in our experiments with this resonance bottle ranged from *e* to *e'*. We had thus a constant cavity producing unmistakably the same vowel throughout an octave.

Table VII. gives the constituents of each *ō* thus artificially produced. They agree with the *ō*'s pronounced by the voice in being composed of a prime and its octave for notes above *b*, also in having the first three partials on *e* and *f*♯. On *g* the third is stronger than in the human voice. No specially strong reinforcement appears to exist in this artificial *ō* for *b'♭*, or any tone near it, but there is a wide range of reinforcement extending on both sides of this pitch. It may be stated that this artificial *ō* was what might be called a bright *ō* whose pitch of general or of maximum resonance might be expected to be somewhat higher than that of the *ō*'s given by the human voice.

We draw attention to the fact that even supposing the prime not to have been reinforced at all, this irregular gutta-percha cavity must have reinforced tones, more or less strongly, through a range of at least fifteen semitones, namely, from *e'* to *g''*. This fact follows from the analyses, but it was confirmed by another and independent experiment. A short tube was inserted into the bottle in place of the reed and the end of the tube applied to the ear so that the cavity acted as a resonator to sounds from outside. The keys of a piano were then struck in succession and the listener noticed by the bumming noise in the bottle what tones were reinforced. On working down the scale resonance was first noticed at *g''*♯. It increased, and became excessively strong on *f''*, and remained nearly equally strong on *e''*. It then diminished a little, but became very intense again on *c''*♯, then diminished again, but even on *g'* and *f'*♯ it was much stronger than could be accounted for by the strengthening of the second partial. Below this the experiment was not suited to detect the influence of the cavity as a resonator on account of the reinforcement of upper partials in the notes struck. It sufficed, however, to prove that this irregular cavity possessed not only one, but probably several proper tones, so near to one another as to give the effect of a resonator strengthening, more or less, every tone between widely distant limits.

We have also made a few experiments on the vowel sounds "awe" and "ah," which we shall write *a*° and *ā* respectively. The phonograph spoke these sounds fairly well, though not quite so well as the sounds *ō* and *ū*. It may here be remarked that our phonograph was not capable of registering very high tones; a shrill whistle, however loud, produced no effect on the tinfoil. This fact proves, independently of the analyses, that in the case of those vowel sounds which it did speak well, the comparatively low partials were sufficient fully to characterise the vowel. The observations show that for *a*° the first three partials are prominent where *ō* has only two; and that for the same part of the scale *ā* has four consecutive partials all prominent. The fifth partial was considerably strong for *ā* when sung on *e*, where *ō* was composed of three partials and *a*° of four. Tables VIII. and IX. show the analyses made of these two vowels as sung by voice 5.

This communication is already so long that we must defer our general remarks to another number. FLEEMING JENKIN
J. A. EWING

EXPERIMENTS ON THE RELATIVE SPECIFIC GRAVITIES OF SOLID AND MELTED MATERIALS AT THE TEMPERATURE OF FUSION

DR. MUIRHEAD communicates the following account of experiments undertaken at his request, for the purpose of testing the notion that the earth's crust, as it cooled, became relatively heavier than the molten mass within; that the crust, breaking into fragments, sank; and this process, going on time after time, by and by built up a sort of honeycombed arrangement of the earth's interior:—

"*Railway Works, Leeds*, March 30, 1878

"DEAR SIR,—I have carefully gone over the experiments *re* the melting of metals in contact with liquid metals. I was certain on this point, from more than half a century's observation, before you wrote me, and I think I stated that conclusion in a former letter. I have now only to indicate the order in which I conducted the experiments, the result of which I now communicate.

"With several different compounds of brass, at various temperatures, I melted similar compounds; skimming the metal in the crucible, I laid the solid piece carefully on the clean surface, which piece, coating itself partially by chilling the liquid metal, very soon re-absorbed a sufficient amount of heat to be fused,

and, fusing from the *bottom side*, gradually dissolved. I then placed similar blocks of metal endwise on, when, dipping beneath the surface, they bounded back to the surface, and subsequently dissolved, endway down. These results apply to various weights and sorts of compounds. I then conducted similar experiments with cast-iron, and found that the facts were still more conspicuous in the cast-iron (all of the same tendency) than in brass.

"Placing the iron on the surface of the liquid iron, a rapid chill set in, and a coating of iron, apparently about ⅛" thick, attached itself to the cold iron, but very shortly re-melted, when the cold iron disappeared with it. I then dropped a small piece of cold iron (the same being dried to prevent explosion) endwise on to the surfaces of the liquid metal, when, bounding back to the surface, it melted in that position.

"The argument applies precisely to the experiments conducted in lead.

"In all cases the cold metals were relieved of any exterior ingredient by being well filed over. In every case of brass and iron the material melted was about 1" in diameter and 4" in length, each piece being round. With regard to the lead, the pieces varied in size, weight, and form, but all the experiments resulted in the same way. "JOSEPH WHITLEY"

"*Railway Works, Leeds*, April 11, 1878

"MY DEAR DR. MUIRHEAD,—Confirming my letter of yesterday, I have now to report the results of several experiments which, you will see, perfectly coincide with and demonstrate the truth I have again and again assured you of, viz., that all liquid matters that are susceptible of solidification will, when solid, float upon similar matter when in a liquid state.

"I intimated to you in my last that I feared I could not, in a small crucible, sufficiently fuse granite and whinstone, and in my experiments of yesterday, although I melted my crucible, I did not sufficiently liquefy the granite so as to float a piece upon the liquid mass. I therefore deferred further manipulations till to-day, and having secured a quantity of whinstone, I also determined to alter my course and to take advantage of a much larger focus of heat than that of a furnace 30" × 20" × 20", with a 60-lb. crucible. So I called upon Messrs. Taylor Bros. and Co., ironmasters of this town, and with their permission I proceeded as follows:—

"Being passed over by their manager to a subordinate officer—a worthy and very intelligent fellow, and, by the way, a strong believer in the doctrine that matter sinks in like matter when melted—we went to a furnace where we had three tests with whinstone, which he said disappeared, and I believe that he was justified in the two first experiments, because he was not sufficiently up in his observation as to notice a stream of gas liberated from a bubble formed on the surface by the melting of the whinstone immediately under it. In the next furnace we went to we had a large quantity of liquid 'cinder' 'tapped out' of a furnace into a trough. I really wish you could have seen it; to me the sight was grand, the gases given off by the melting of the whinstone blazed with a sort of blending of tints of purple, yellow, and green. I never saw anything so fine in flame. The whinstone was like a thing of life, so buoyant—of course the specific gravities of the liquid and solid materials varied considerably, and hence the buoyancy of the whinstone. We then tried a large number of small pieces of cinder—same as the liquid mass before us; but my friend the officer insisted that they went to the bottom—they certainly, except in one instance, never returned to the surface, because they liquefied before they had time to rise. My whinstone being done, and seeing that the results were not so satisfactory to my friend, I remarked that I was prepared to go all day and all night rather than give up the task of convincing him that his conclusions were wrong. I therefore suggested we should take a larger furnace, and deal with larger masses. We therefore, instead of dealing with quantities of 8 oz. weight, and weights of 1 lb., took pieces of 5 and 6 lbs. weight, each of solid cinder. Had my faith not been implicit I might have been deceived, for No. 1, 2, and 3 pieces went to the bottom, and my friend said, 'Now are you satisfied?' and I replied 'No, I am not.' Imagine his astonishment when No. 1 came bounding to the surface, and floated about like a cork, when the mass of heat had dissolved the coating which it clothed itself in at entering the bath and had begun to melt the original piece, up came No. 2 and 3, and I let him float them about on the surface with an iron rabble, so as to sear, as it were, the lesson sufficiently deep into his soul that it might never be erased. There were eight or nine jolly fellows looking on, and who enjoyed the joke, when my friend took off his hat and bowing politely said, 'Well, I am exceedingly obliged for the lesson you have taught me, and I shall never forget that all solid matter floats upon like matter when melted, as ice floats upon water.' Of course I had a joke and told him he was only one of a few who believed in the doctrine, and that he was the last convert. "JOSEPH WHITLEY"

P.S.—In the name of science I take this opportunity of tendering to Messrs. Taylor Bros., of the Clarence Iron Works, Leeds, my grateful thanks for their generous acquiescence in my request, and the facilities they kindly rendered in the experiments.—J. W.

THE INFLUENCE OF LIGHT UPON BIOPLASM[1]

SOME twelve months ago we briefly recorded in NATURE the results of our observations on the effect of sunlight on bacteria, and other organisms commonly associated with putrefaction and decay. Most of the experiments were subsequently described in detail in a paper communicated to the Royal Society. The chief of our earlier conclusions may be summed up shortly as follows:—

1. Light is inimical to, and under favourable conditions may wholly prevent, the development of these organisms, its action on the common forms of bacteria being apparently more powerful and rapid than upon the mycelial fungi which are prone to appear in cultivation-fluids.

2. This action appears to attain its maximum in the waves of greatest refrangibility. It is demonstrable in yellow light, but towards the red end of the spectrum sinks to a minimum.

3. The fitness of the cultivation-fluid to act as a nidus is not impaired by the insolation.

We found, moreover, that tubes containing a cultivation fluid and plugged with cotton wool, when removed to a dark place after exposure to the sun for a sufficient period remained perfectly clear and free from organisms for months. We thought, therefore, that the "germs" in these solutions had been completely destroyed by the solar rays.

While, however, we believe that, if the insolation be sufficiently prolonged, all the germs or spores originally present may be killed, and that, as regards bacteria, the insolation, under favourable conditions, need not be of very long duration, we have reason to think that, by *cell-walled* organisms, the destructive action of light may be resisted for a considerable period, and that the first result is to reduce the spore to a state of torpidity in which it may lie dormant for many months.

The investigation of this point, however, must necessarily extend over a long time; and in the above remarks we would wish to be understood as offering a suggestion rather than a definite conclusion.

We noticed last year that sunlight had no retarding effect on the *action* of the "indirect ferments," or, at least, of the soluble ferment of yeast (*zymase* of Béchamp, *ferment inversive* of Berthelot), which we used for our experiment. More recently, however, we have tested the effect of prolonged insolation on the soluble ferment itself, and have found that, at the end of three weeks' exposure to a midsummer sun, the *zymase* had entirely lost its characteristic property of hydrating cane-sugar, while a corresponding specimen, which had been kept in the dark, still retained its energy. It would appear, therefore, that the action of light affords no means of distinction between the "organised" and the "indirect" ferments.

We have attempted to elucidate the intimate nature of this action of light upon the organisms which have formed the subject of our experiments, and we have evidence pointing strongly, as we think, to the solution of the problem. Early in 1877 we set ourselves to this task, and, in order to obtain some insight into the effect of light upon certain organic bodies, we made a number of observations upon oxalic acid.

We have elsewhere[2] shown that a solution containing 0·63 per cent. (decinormal) is entirely decomposed by a somewhat prolonged exposure to strong sunlight when air is present. We now find that in a corresponding solution, *in vacuo*, no change

[1] By Arthur Downes, M.D., and T. P. Blunt, M.A. Oxon.
[2] *Chemical News*.

whatever is produced. This points conclusively to oxidation as the cause of the phenomenon.

We may here remark that this conclusion agrees with the results of the recent observations of M. Chastaing[1] upon a number of organic bodies, which he found to be oxidised under the influence of light.

As regards our oxalic acid, we have also determined that the oxidation in this instance is probably of the hydrogen and not of the carbon of the molecule.

From analogy and from direct experiment we believe that the mode in which light injuriously affects the organisms with which our investigation deals, is neither more nor less than a gradual oxidation of their living bioplasm, similar to the oxidation of the comparatively simple molecule of oxalic acid.

There is a lingering belief in the minds of many that matter which is endowed with life can by its "vital resistance" the more endure and survive the effect of injurious influences. This belief, derived, perhaps, like many others from a misapprehension of the indirect for the direct and from a misapplication of analogies, has no support from our experiments. On the contrary, we have met with results which are best explained by the consideration that bioplasm is matter of the utmost complexity and instability of constitution, ever-changing and most instable when the vital forces are at their full. We believe, in a word, that instability of this life-stuff is a predisposing cause for the destructive action of light, while in its stabler conditions it is more resistant.

We wish to keep this note within the limits of brevity, and will only remark in conclusion that, since the organisms which have been the subject of our work may be regarded as "life-units," well fitted by their tenuity for the demonstration of the action of sunlight upon the "physical basis" of their life, we may reasonably expect, and, indeed, may see, that this action is not limited to these special cases. We have chosen, therefore, in the heading of these remarks, to indicate the wider field of their application, but we by no means wish to imply that the relations of light to bioplasm are in all cases so simple.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

AT the Graduation Ceremonial in Medicine and Law in connection with the University of Edinburgh held on August 1 the honorary degree of LL.D. was conferred on James Risdon Bennett, M.D. Edinburgh, F.R.S., President of the Royal College of Physicians, London, Sir Joseph Fayrer, M.D. Edinburgh, K.C.S.I., F.R.S., John Richard Green, M.A. Oxon, Joseph Lister, M.B. London, F.R.S., lately Professor of Clinical Surgery in the University of Edinburgh, and now of King's College, London.

AT the annual meeting of the Council of the Royal School of Mines the prizes were awarded as follows:—The two Royal Scholarships, of 15*l*. each, for first year's students, to Mr. R. G. Scott and Mr. W. Cross; the Royal Scholarship, of 25*l*., to Mr. R. Lancaster; the Edward Forbes medal and prize of books, to Mr. P. F. Frankland; the De la Beche medal and prize of books, to Mr. F. G. Mills; the Murchison medal and prize of books, to Mr. M. Terrero; and an extra medal to Syed Ali.

MRS. CATHERINE DAUNTESEY FOXTEN has bequeathed to Owens College, Manchester, the sum of 5,000*l*. to found two scholarships, one Legal and the other Medical.

WORK has been commenced on the extensive edifices of the new Berlin Polytechnic, which is to be situated a short distance out of the city at Charlottenburg. Five years are expected to elapse before the completion of this much-needed institution.

THE city of Lille has received from the French Department of Education the sum of 50,000 francs to assist in the foundation of a medical school.

THE Imperial ukase announcing the foundation of the new Siberian University states that it shall number four faculties, the medical, the legal, the historico-philosophical, and the physico-mathematical. Orders have been issued for the prompt construction of the edifices, towards the expense of which the provincial government of Tomsk has already appropriated 250,000 roubles—about 35,000*l*.

SCIENTIFIC SERIALS

Kosmos, April.—On life in Kosmos, by Carl du Prel, discussing possibilities of life in other worlds than ours.—The kingdom Protista, first part, by E. Haeckel.—On the physiology of the new-born, by M. Preyer. Part 1: On hearing and sight.—On the nests and gardens of *Amblyornis inornata*, or, rather, theories about them, by O. Beccari.—The sway of ceremonial, by Herbert Spencer. Part 4: On presents.—The discontinuance of human sacrifices, by E. Krause.

May.—The kingdom Protista, by E. Haeckel, describing Amœba, Protococcus, Euglena, Flagellata, Volvocina, Noctiluca, Infusoria, Acineta, Rhizopods, Foraminifera, and Radiolaria; forty-one excellent woodcuts.—On the physiology of the newly-born, by M. Preyer; on smell and taste.—The animal kingdom, as regards similarity of adaptations, by W. von Reichenau.—The sway of ceremonial, by Herbert Spencer: On marks of honour.—Sexual selection in plants, by W. Focke.

June.—Contribution to experimental æsthetics, by Rudolf Redtenbacher, pursuing Fechner's researches and discussing his results, analysing the causes of pleasure as regards the shapes and textures of flat surfaces, as well as of crystals.—Ernst Haeckel continues his popular articles entitled "The Kingdom Protista." He diverges very much into theory as usual, expounding his doctrine that the true animal kingdom is defined by the formation of a gastrula in its embryonic stage. On the side of phylogeny he considers the protista ascended to true animalism by becoming parasites.—Fritz Müller describes the queens of the Meliponæ, investigated in Brazil. He finds in four species the queens, or in some cases the parthenogenetic females, extraordinarily alike, while the males and workers are very different.—Herbert Spencer's sixth paper on the sway of ceremonial deals with forms of address; these articles are extracted from the future second volume of "Sociology."

Zeitschrift für wissenschaftliche Zoologie, vol. xxx. part 4.—On the origin of the sexual products in hydroida, by J. Ciamician; two plates of tubularia and endendrium.—Further contribution on the genus analges or dermaleichens (crustacean), by G. Haller; three plates.—On the structure of *Reniera semitubulosa* (sponge), by E. Keller; two plates.—On the structure of the Malpighian vessels of insects, by E. Schindler; 74 pages, three plates.

Vol. xxx., supplement, part 2.—Anatomical and zoological observations on the amphipods and isopods, by F. Leydig; fifty pages, four plates.—On the development of the testes and the alternation of generations in the salpæ, by W. Salensky.—On a mathematical method in zoology, illustrated from the acarida, by P. Kramer.—The reproductive organs of some ectoparasitic trematodes, by Carl Vogt; four plates, thirty-seven pages.—On the movements of "flying fish" through the air, by Karl Möbius; one plate, forty pages; giving an account of all observations on the movements of these fish, the anatomical structures on which they depend, and the way in which the mechanism works.—Studies of the freshwater fauna of Switzerland, by F. A. Forel. He distinguishes the characters of the littoral, the pelagic, and the deep-sea fauna of Lake Leman; discusses the relations between the present fauna and that of recent geological periods, and the migrations of species; and concludes that the lacustrine fauna of the subalpine waters has entered by migration since the glacial period; that the littoral fauna has come from other lakes of other lands; the pelagic fauna from forms already differentiated as such before migration; and the deep fauna by modification from the littoral.—On mud-dwelling cladocera, by W. Kurz; one plate, eighteen pages.

Vol. xxx., supplement, part 3.—On the early embryonic development of *Tendra zostericola*, by W. Repiachoff, one plate.—On the comet-forms of star-fishes, with a discussion of the phylogeny of the echinodermata, by E. Haeckel, one plate.—Contributions on protozoa, by A. Schneider: on actinosphœrium; on development of miliola; on trichosphærium and chlamydomonas, one plate.—On the form and signification of organic muscle-cells, by W. Flemming. The author believes he has discovered the development of unstriped muscle-cells in *Salamandra maculata* out of connective tissue cells, one plate.—On the anatomy of the entomostracan *Limnadia hermanni*, by F. Spangenberg.—Studies on the history of the Polish Tur, by A. Wrzesniowski. In this exhaustive paper of sixty pages all the historical references are examined, and most interesting woodcuts copied from representations of two animals are given. The conclusion is that two of the Bovidæ

remained extant in Poland to comparatively recent times, viz., *Bos primigenius* and *Bison europæus*, and that the former was the last to die out, in the beginning of the seventeenth century.—On the unity of the structure of the brain in the different orders of insects, by J. H. L. Flögel, illustrated by two plates of capital photographic reproductions of microtome-sections, thirty-seven pages.—On *Archigetes sieboldi*, a sexual cestode-nurse, by R. Leuckart.—The epiphysis on the brain of plagiostomes, by E. Ehlers, illustrated by two plates from *Raia clavata* and *Acanthias vulgaris*.

Bulletin de l'Académie Royale de Belgique, No. 5, 1878.—This number contains a memoir by M. Firket, treating of geological and chemical phenomena which have altered the rocks of an important metalliferous region in the province of Liége. The first part refers to the silurian fault and the metalliferous veins of the Champ d'Oiseaux; the second to the constitution and course of beds of oligiste; and the third to epigenic transformation of oolithic oligiste into siderite, in contact with a vein of pyrites (*à propos* of metalliferous veins of the mine of Landenne).—M. Spring, having conceived some doubts as to the existence of pentathionic acid, has examined anew the so-called pentathionates of potassium and baryum, and he finds these tetrathionates instead of pentathionates.—M. van Beneden announces the discovery of some gigantic fossil reptiles (probably Iguanodon) in the coal formation of Bernissart, near Peruwelz; and there is some correspondence between Count Du Moncel and MM. Navez on the subject of the telephone.

Reale Istituto Lombardo di Scienze è Lettere, Rendiconti, vol. xi. fasc. x.—We note the following papers in this number:—Critical annotations on duodenal anchilostoma, by Prof. Sangalli.—Causes and circumstances which influence hereditary transmission in animals (continued).—Hereditary transmission in the act of fecundation; note by Prof. Lemoigne.—Cure of varicocele by means of the temporary sub-cutaneous elastic ligature, by Prof. Scarenzio.—First lines of a cardiographic study designed for clinical purposes, by S. de Giovanni.—On the electromotive force developed from saline solutions of different degrees of concentration, with metals which do not form the base, by Prof. Cantoni.—*Résumé* of meteorological observations at Milan, in the Royal Observatory of Brera in 1877, by S. Fisiani, Jun.

The Journal of the Russian Chemical and Physical Societies (vol. x. No. 6) contains the following more important papers: On the action of iodide of butyl upon isobutylene in the presence of metallic oxides, by Miss Julie Lermontoff.—On quinine and cinchonine, by A. Wischnegradsky and A. Boutlerow.—On the fatty acids which are formed by the action of alkali upon cinchonine, by M. Lubavin.—On the hexylenes resulting from tertiary hexylic alcohols, and on their condensation, by L. Tavein.—On the preparation of bromide of trimethylene, by T. Bogomollez.—On the structure of the hydrocarbon $C_{19}H_{14}$ resulting from chloride of triphenyl-carbinol, by V. Hemilian.—On the anhydride of glyceric acid, by N. Socoloff.—On the formation of albumen from one of its products of decomposition, by A. Danilewsky.—On the action of bromine upon the compound homologues with benzol in the presence of bromide of aluminium, by G. Gustavson.—On diallylpropylcarbinol, by P. and A. Saytzeff.—On the conversion of primary alcohols into ethers, by N. Menschutkin.—On the theory of the current, by P. Van der Vliet.—On the resistance of steel, by M. Picatscheff.

SOCIETIES AND ACADEMIES

PHILADELPHIA

Academy of Natural Sciences, January 29.—On the mode of recognition among ants, by Rev. H. C. McCook.—Notes on the natural history of Fort Maçon, North Carolina, by Dr. Elliot Coues and Dr. H. C. Yarrow.—Description of new invertebrate fossils from palæozoic rocks of Illinois and Indiana, by Dr. C. A. White.

February 5.—Note on *Calycanthus floridus*, by Mr. T. Meehan.

February 26.—On the alkali of the plains in Bridger Valley, Wyoming, by E. Goldsmith.—On the mechanical genesis of tooth-forms, by J. A. Ryder, an important paper on mammalian teeth.

March 26.—On the electric constitution of the solar system, by Jacob Ennis.

April 2.—On the toilet habits of ants, by Rev. H. C. McCook.—On the Basilica spider and her snare, and on the probable geographical distribution of a spider by the trade winds, by same author.—Notes on *Acer rubrum*, by Mr. T. Meehan.

April 6.—On the vegetative repetition of cerebral fissures, by Dr. A. J. Parker.

PARIS

Academy of Sciences, July 29.—M. Fizeau president, in the chair.—New communication on the subject of the notes on alcoholic fermentation found among the papers of Cl. Bernard, by M. L. Pasteur. M. Pasteur finds that the notes, as printed in the *Revue Scientifique*, are in several places incorrect; M. Pasteur intends to repeat Bernard's experiments. M. Berthelot made a few observations on M. Pasteur's communication.—On the variations of the intensity of currents transmitted across mediocre contacts, according to the pressure exercised upon them, by M. Th. Du Moncel.—Absorption by the living organism, of carbonic oxide introduced in determined proportions into the atmosphere, by M. N. Gréhant.—On the *rôle* of coal dust in the production of explosions in mines, by M. L. Simonin.—New theory of the alterations caused by the phylloxera on the roots of the European vine, by M. Millardet.—Observations of the periodic comet of Tempel, made with the equatorial of the garden of the Paris Observatory, by M. Pr. Henry.—On the covariants of binary forms, by M. C. Jordan.—Note on a theorem on relative movements, by M. Laisant.—On the non-existence of the lengthening of a conductor traversed by an electric current, independently of calorific action, by M. R. Blondlot.—New observations on the subnitrates of commercial bismuth, by M. A. Carnot.—Thermic formation of phosphoric hydrogen and of arsenious hydrogen, by M. J. Ogier.—Researches on amylic alcohol (continued); dextrogynous alcohol, by M. J. A. Le Bel.—On the identity of the inulines of various origins, by MM. Lescœur and Morelle.—On the diffusion of salicylic acid in the animal economy (presence in the cephalo-rachidian liquid), by MM. Ch. Livon and J. Bernard.—On the anatomical characters of the Aye-Aye, by M. Edm. Alix.—On the influence of leaves in the production of sugar in beet-root, by MM. B. Corenwinder and G. Contamine.—Age of the bed of Mont Dol (Ille-et-Vilaine), by M. Sirodot.

THE COMING ECLIPSE

WHEN I wrote two articles in NATURE a little while ago, discussing the various methods which I thought might with advantage be employed next Monday, I little thought that it would fall to my lot to come to America to take part in the observations. The fates, however, have so ruled it, and here I am, in what was not long ago called the "Great American Desert," but by no means a martyr to science; for, although Rawlins—where I now am—is nearly 7,000 feet high, and near the Rocky Mountain divide; although elk and antelope may be shot within a mile of the town; yet the sluggard is roused at six by the voluminous steam whistle of the railway works: there is a thriving "city" and population.

The energy displayed by the American astronomers is, if possible, greater than I anticipated. There is scarcely a man of note among them who is not now along the totality line which runs from the Yellowstone Park to the Gulf of Mexico. Where the wonderful Union Pacific Railway cuts the line east and west there will be four stations—Rawlins, Separation, Fulmore, and Creton. Along this line will be gathered Professors Newcomb, Harkness, Draper, Watson, with their many assistants. In the middle region, including Denver Central City, and Pike's Peak, will be Professors Young, Holden, Langley, Cleveland Abbe, and General Myer, the chief of the Weather Signal Service. The parties under these are many of them numerous, Prof. Young's camp, for instance, including thirteen persons. In the southern region, at Pueblo and Los Animas, Prof. Hall heads a large party, including Prof. Wright, of Yale, and Prof. Thorpe and Dr. Schuster from the old country.

In all three groups of stations the various kinds of work have been divided in a most judicious manner. In all attempts will be made to obtain the spectrum of the chromosphere and coronal atmosphere in the way suggested in my previous articles; in all the structure of the coronal atmosphere will be carefully inquired into. So far as photographs of the corona are concerned, perhaps the strongest attack will be made by an impromptu party not referred to in the preceding enumeration. On my way here from Cheyenne it was my great good fortune to travel with Prof. Hayden, *facile princeps* among the great geological surveyors of this vast continent. He was on his way to the north, and, as usual, had with him a strong photographic equipment. As his march lies along the line of totality, he will obtain, or at all events endeavour to obtain, a large series of photographs.

It is agreed on all hands that never has such summer weather been known in this locality. Ordinarily the chances, as determined by the officers of the signal service from their registers, are—Northern stations, 80 per cent.; Denver, 60; Pike's Peak, 40; and Los Animas, 80; but here, for the last fortnight, fine mornings have been succeeded by a break-up in the weather in the afternoon, while at Denver matters have been much worse.

A most valuable second series of instructions, written by Prof. William Harkness, of the United States Navy, by direction of Admiral Rodgers, has been published. Of these Sections I., II., V., and VIII. describe such observations as can be made with ordinary apparatus, while the other sections relate mostly to observations which can only be carried out by persons who are able to command expensive apparatus, and who are skilled in astronomy and physics.

This is a most useful following up of the work of organisation undertaken in England for the first time in 1870 and carried out in 1871 and 1875.

Prof. Harkness has freely availed himself of the Instructions compiled for the English Expeditions of those years, and in his carefully written memorandum has given us an opportunity of seeing how the problems have been advanced of late years; he has also collected a valuable series of data which give permanent value to it. I do not think I can do better than refer to some of the more important points touched on in the Instructions.

All the most rapid varieties of lenses in the market suited for use as equatorial cameras are given in the following table, in which the corresponding intensity ratios have been taken from Dallmeyer's catalogue.

Reference No.	Description of photographic objective.	Intensity ratio.[1]	Focal distance of largest lens made.	Diameter of image of sun.	Exposure required for the corona.
			Inches.	Inches.	s. s.
1	Extra quick acting portrait	$\frac{1}{2}$	$5\frac{1}{2}$	0·051	0·3 to 1·6
2	Quick acting portrait ...	$\frac{1}{3}$	$13\frac{1}{2}$	·126	0·7 to 3·6
3	Ordinary portrait	$\frac{1}{4}$	24	·224	1·3 to 6·4
4	Portrait and Group (D) ...	$\frac{1}{6}$	33	·308	2·9 to 14·4
5	Rapid rectilinear	$\frac{1}{8}$	$33\frac{1}{2}$	0·313	5·1 to 25·6

Prof. Harkness points out that "the data from which to determine an approximate value of C for the corona are very limited." He considers that it is probably safe to conclude that, with a clear sky and a moderately high sun, exposures in which the value of C is about 0·002 will give only the prominences and the outline of the moon. When C becomes 0·08 the corona will begin to appear, and will increase in extent as the exposure increases, at least up to the point where C becomes 0·40. Accordingly, the shortest exposure specified in the table above corresponds to $C = 0·08$, and the longest to $C = 0·40$.

If we adopt a lens of thirty-three inches focus an attempt can be made to use the lens for another purpose, "even more important than photographing the corona," that is in the search for intra-Mercurial bodies. Prof. Harkness points out that the magnitude of its intensity ratio enables it to depict faint objects rapidly, and the extent of its angle of view is such as to embrace a field of more than forty degrees. The lens will cover a plate measuring twenty by twenty-two inches, but as it is desirable to keep the apparatus light, plates measuring seventeen by twenty inches, which will suffice to cover a space of thirty-three and a half degrees along the ecliptic, are recommended.

[1] If F is the equivalent focal distance of a photographic objective, d it working aperture, C the exposure constant, whose value depends upon the intensity of the light and the sensitiveness of the chemicals employed, and the time of exposure required to produce a good negative, then the intensity ratio is $\frac{d}{F}$, and $t = C\left(\frac{F}{d}\right)^2$.

"Assuming the adoption of an equatorial camera twenty inches square, provided with a lens whose intensity ratio is one-sixth and whose focal distance is about thirty-three inches, it yet remains to consider how this apparatus should be managed during a totality lasting only three minutes. As the illumination of different parts of the corona varies greatly, there can evidently be no certainty of geting all the details of the phenomenon unless a series of plates are taken, in which the exposures vary from the shortest possible up to the point where it is certain that an increase of time does not improve the picture. On this account it will be desirable to take as many as six plates, the exposures being, respectively—

3^s, 5^s, 10^s, 20^s, 40^s, and 60^s.

The first four of these plates will receive such short exposures that it is unlikely they will show anything but the corona, and therefore their size should be 4¼ by 5½ inches. With the last two plates the case is different. Their size should be 17 by 20 inches, because their longer exposures will probably suffice to bring out upon them any bright points which may exist within their field. A lens such as is here under consideration should depict an eighth-magnitude star in about one minute, but of course the intensity of the sky-illumination during totality will determine the limit of brightness at which faint luminous points will cease to impress themselves upon the negatives, and what this limit may be it is impossible to predict. The necessity for at least two large plates is evident when it is remembered that the image of a small bright point could not be distinguished from an accidental blemish in the film, and it would only be by finding it upon both plates that its true character could be unmistakably recognised. It is exceedingly desirable to determine accurately the maximum exposure that the corona will bear with advantage, and it is hoped that on at least one of the large plates it will prove to be over-exposed."

It has been proposed to photograph the red prominences on a scale of ten seconds of arc to a millimetre. The optical apparatus for the production of such pictures must have an equivalent focal distance of 2062·7 centimetres, or 812·1 inches, and if we take C equal to 0·002, which is probably very near the truth, the value of t for lenses of various apertures are given as follows in the instructions :—

Aperture of objective.	$\frac{F}{d}$	$\left(\frac{F}{d}\right)^2$	Exposure required.	Motion of moon.
Inches.			s.	"
6	135·3	18306	36·6	20·1
8	101·5	10302	20·6	11·3
10	81·2	6593	13·2	7·2
12	67·7	4583	9·2	5·0
15	54·1	2927	5·8	3·2
20	40·6	1648	3·3	1·8
26	31·2	973	1·9	1·0

As a prominence one minute high could scarcely be photographed with a six-inch objective, because twenty seconds of its height would be covered by the advancing moon before the exposure was over, Prof. Harkness thinks it does not seem possible to photograph prominences during eclipses on the scale here contemplated with an aperture much less than ten inches.

The section relating to telescopic observation is very full and complete ; full instructions concerning the structure of the corona are given, and the remark is made that "Since the spectroscope furnishes an efficient means of studying the red prominences at any time, it will be very undesirable to waste a single one of the precious moments of totality in examining them."

To facilitate the work of such astronomers as may desire to search for intra-Mercurial planets with considerable telescopic power, a chart is given showing every star so large as the seventh magnitude in that portion of the heavens which will be occupied by the sun on the 29th of July next. The black circle in R.A. 8h. 36m. Dec. + 18° 39′ indicates the position of the sun. Mercury, Regulus, and Mars will be pretty close together, and probably quite conspicuous during totality, but they are so far to the eastward that only the last-named comes within the limits of the chart. Venus may also be seen, but she will be low in the western sky. While looking for planets, the possibility of discovering a small comet, or a meteor stream, should be borne in mind.

"The corona forms a luminous background upon which the moon's limb is sometimes seen projecting beyond the sun ; and a little before totality it is even possible that the complete outline of the moon may become visible. Look for these phenomena, and note the time of their occurrence. It is difficult to assign any reason for the existence of rays, or brushes, of light at the cusps of the sun, but it is said they have been seen. If any such appearances present themselves, they should be carefully scrutinised to ascertain if they change either their position or intensity ; and the interior of the telescope should be examined to make sure that they do not originate in reflections, either from the tube or from the lenses."

The instructions as to the use of the spectroscope and polariscope are so full that they deserve reprinting *in extenso*. I shall therefore say nothing about them here except to express my belief that no stone has been left unturned to secure results, if results be possible. Spectroscopically, I suppose Dr. Draper and Prof. Young have the strongest outfit, while, so far as I know, Prof. Harkness is the only one who is equipped for photographing the polarisation of the corona.

For the first time thermo-electric observation forms part of eclipse work. One of the many points of interest here, to me, has been the observatory in which Mr. Edison has been experimenting on his tasimeter. It is truly a very wonderful instrument, and from the observations made last night on the heat of Arcturus, it is quite possible that he may succeed in his expectations. For its extreme delicacy I can personally vouch. The instrument, however, is so young, that doubtless there are many pitfalls to be discovered. Mr. Edison, however, is no unwary experimenter.

So much, then, for the present. The day after tomorrow will find us all busier than ever, and if the weather prove fine I hope I shall have, as in 1870 and 1871, another distinct advance in solar physics to chronicle.

J. NORMAN LOCKYER

Rawlins, Wyoming Territory, July 27

OUR NATURAL HISTORY COLLECTIONS

THE Bill to enable the trustees of the British Museum to remove the natural history collections to South Kensington, on which we commented in our issue of August 1, has passed both Houses and virtually become law. The measure having been introduced at a late period of the session, and hurried through all its stages, evidently for the express purpose of eluding observation, it could hardly have been expected that the result would have been otherwise. The assent of the Treasury was of course secured before the Bill was introduced, and it is by no means surprising that, what with Cyprus and Turkey, and the enormous pressure of other more interesting business, it was never discovered by the Government that the Bill was exactly contrary to the recommendations of the Royal Commission on Science. So far, therefore, the trustees have it all their own way, and are now authorised to continue at South Kensington the system of government that has made the state of our national natural history collections at Bloomsbury so long a byeword amongst naturalists. There remains, however, still one more chance of introducing some salutary reforms into the present system. Following on the authority to remove the collections, which the trustees have now obtained, money will be required to carry out the transfer, and to obtain the requisite funds a fresh application to Parliament will be necessary.

This application will, no doubt, be made in the ensuing session, but before it is complied with we trust that some sort of terms will be obtained from the trustees. In the first place they should be required to delegate the control of the New Natural History Museum to a small committee, in which should be included the two or three naturalists who now happen to be members of the trust. It is obvious that most of the great dignitaries of state and eminent noblemen who form the trustees of the British Museum, neither know nor care anything about natural history. Until recently, indeed, there has not been a single person who could fairly be called a naturalist on the trust. Lately, however, two excellent naturalists (Sir John Lubbock and Lord Walsingham) have become ordinary members of the trust, and Sir Joseph Hooker, as president of the Royal Society, is *ex officio* one of the trustees. A committee consisting of these gentlemen and of a few others, who might be presumed to have some general acquaintance with the requirements of modern science, would, we need hardly say, completely command the confidence of naturalists, and would answer to the board of visitors, which the Royal Commission on Science in their Report suggested should be constituted to look after the director. In the second place the chief executive officer of the new museum should be appointed secretary to the trustees *ad hoc*, and the estimates for the two buildings should be kept entirely separate. So long as there remains any sort of subordination of the natural history to the principal librarian, who is the sole executive officer of the trustees at Bloomsbury, the old policy will be continued. The natural history will be starved in order to feed the overgrown library, and the petty restrictions and regulations which have so long vexed the souls of the visitors to the British Museum will be continued at South Kensington. The best chance of obtaining the necessary reforms lies in an entire change of administration, and for this reason it is much to be lamented that the recommendation of the Royal Commission on Science to place the New Museum of Natural History directly under the control of the Government has not been attended to. Still if the Trustees can be induced to commit the management of the new institution to a well-selected delegacy and to appoint a director free from the evil influence of Bloomsbury, there is every hope that our New Museum of Natural History may be worthy of the nation, and take rank with the sister institutions of Paris, Leyden, and Berlin.

THE BRITISH ASSOCIATION

DUBLIN, *Monday*

TO-DAY the Reception Room was opened in Trinity College, the Examination Hall being used for this purpose; and the doors were scarcely opened before a rush for tickets took place, and 500 associate tickets were sold in the course of two or three hours. As usual, the local honorary secretaries are working vigorously, and so far the arrangements they have made seem to be excellent; in fact, it is generally admitted that at few places has the British Association had so excellent a reception nor so convenient and complete accommodation. One feature in this meeting is the shilling lunch tickets, which every member can procure, and that entitles him to an excellent lunch, costing at least double the price of his ticket. The numerous foreign visitors have been lodged at the chief hotels, and private hospitality has been offered to the leading members of the Association who have announced their intention of being present.

With regard to a paragraph in a contemporary on the soreness which has been produced in Dublin by the cavalier treatment local scientific men have received from the Council of the Association, and stating that local papers would be withheld, we are able to contradict the latter part of this statement, although it cannot be denied that considerable umbrage has been given by the singular omission of some most distinguished local names from the first list of sectional officers; notably is this the case in Section G, Mechanical Science. But the list is stated to be incomplete, and doubtless the omissions will be repaired at the first meeting of the General Committee before these lines are published.

The guide-book which is issued to the Association has each year become a more and more important work, and that to Dublin is certainly the most complete and most carefully compiled of any that we have seen. Nine months ago a guide-book committee was formed, and this committee, after breaking up into different sections, has worked unremittingly to make their undertaking as accurate and complete as possible. No better editors could have been chosen than Professors MacAlister and McNab, who, besides the distinguished position they hold in their own departments of zoology and botany, possess an intimate acquaintance with the topography and biology of the neighbourhood, and who, since the beginning of the year, have unsparingly devoted their time to their arduous editorial labours—labours that have been largely augmented by the unexpected and unfortunate delays on the part of the firm of printers to whom the MSS. was first sent months ago. Thus it comes about that a somewhat awkward division is made into two unequal parts; but the division is one created by the printers and not by the nature of the contents. It is right to add that the thanks of the Association are due to Messrs. Dollard for the energy and skill which they have shown in the final printing of the guide-book. The book is illustrated with three maps; the first is a ten-mile to the inch map of the County Dublin; the second an admirable

geological map of the county; and the third in a pocket is a six-inch map of Dublin and the neighbourhood. A concise and valuable topographical sketch of Dublin, by Dr. MacAlister, opens the series of papers, Dr. J. W. Moore having added to this paper an important set of Meteorological Tables, some hitherto unpublished. The Rev. Maxwell Close contributes an important paper on the Physical Geology of Dublin, Mr. W. H. Bailey a paper on the Palæontology of the Neighbourhood, Dr. Haughton on the Mineralogy of the County, J. T. Pim on the Textile Industries, Dr. Emerson Reynolds on the Places of Manufacturing and Industrial Interest in and around Dublin; then follows Historical Notes and Antiquities of Dublin, by Dr. MacAlister, after which an extended and valuable list of the Flora of the Counties of Dublin and Wicklow is contributed by Mr. W. Archer, F.R.S., Dr. Perceval Wright, the Rev. Eugene O'Meara, Dr. D. Moore, Mr. G. Pim, and Mr. A. G. More. The fauna of the county is next dealt with, being compiled by Mr. H. W. Mackintosh, Mr. W. F. Kirby, Prof. W. R. McNab, the Rev. B. W. Adams, Prof. MacAlister, Mr. A. G. More, and Mr. R. M. Barrington. This unique and invaluable guide-book ends with a notice of the more interesting of the corporation records compiled by the Rev. W. G. Carroll.

We have already noticed the extensive preparations made for the *soirée* to be given to the Association by the Royal Dublin Society on Thursday. At this *soirée*, among many other things, Mr. Johnstone Stoney, the honorary secretary of the Society, will show the remarkable absorption spectrum of chloro-chromic anhydride, Mr. Gordon his recent and beautiful experiments on electric induction, and Prof. Barrett the effect of inaudible vibrations on sensitive flames.

One of the special objects of interest to be seen in Dublin is the great telescope Mr. Howard Grubb is constructing for the Austrian Government. We may state that the mechanical part is almost complete; the object-glass, which is to be twenty-seven inches in clear aperture, is of course not ready, as the glass was only received from Paris in the spring of this year. Visitors, however, need not be disappointed, as there is plenty to see in the mechanical details of the instrument and the great forty-five-foot dome for the covering of the telescope, the largest dome ever constructed. We may add, in conclusion, that among other places of interest, a visit to the Royal College of Science on Stephen's Green, with its museum of Irish industries and its excellent equipment of physical and mechanical apparatus, should not be omitted.

Inaugural Address of William Spottiswoode, M.A., F.R.S., LL.D., D.C.L., President.

Introductory.

On looking back at the long array of distinguished men who both in this and in the sister countries have filled the chair of the British Association; on considering also the increased pains which have been bestowed upon, and the increased importance attaching to, the Presidential Address, it may well happen when, as on this occasion, your choice has fallen upon one outside the sphere of professional science, that your nominee should feel unusual diffidence in accepting the post. Two considerations have, however, in my own case outweighed all reasons for hesitation: first, the uniform kindness which I received at the hands of the Association throughout the eight years during which I had the honour of holding another office; and secondly, the conviction that the same goodwill which was accorded to your treasurer would be extended to your president.

These considerations have led me to arrange my observations under two heads, viz., I propose first to offer some remarks upon the purposes and prospects of the Association with which, through your suffrages, I have been so long and so agreeably connected; and secondly, to indulge in a few reflections, not indeed upon the details or technical progress, but upon the external aspects and tendencies of the science which on this occasion I have the honour to represent. The former of these subjects is, perhaps trite, but as an old man is allowed to become garrulous on his own hobby, so an old officer may be pardoned for lingering about a favourite theme. And although the latter may appear somewhat unpromising, I have decided to make it one of the topics of my discourse, from the consideration that the holder of this office will generally do better by giving utterance to what has already become part of his own thought, than by gathering matter outside of its habitual range for the special occasion. For, as it seems to me, the interest (if any), of an address consists, not so much in the multitude of things therein brought forward, as in the individuality of the mode in which they are treated.

British Association, past History.

The British Association has already entered its fifth decade. It has held its meetings, this the forty-eighth, in twenty-eight different towns. In six cities of note, viz., York, Bristol, Newcastle-on-Tyne, Plymouth, Manchester, and Belfast, its curve of progress may be said to have a node, or point through which it has twice passed; in the five Universities of Oxford, Cambridge, Dublin, Edinburgh, and Glasgow, and in the two great commercial centres, Liverpool and Birmingham, it may similarly be said to have a triple point, or one through which it has three times passed. Of our forty-six presidents, more than half (twenty-six, in fact), have passed away; while the remainder hold important posts in science, and in the public service, or in other avocations not less honourable in themselves, nor less useful to the commonwealth. And whether it be due to the salubrity of the climate, or to the calm and dispassionate spirit in which science is pursued by its votaries here, I do not pretend to say; but it is a fact that the earliest of our ex-presidents still living, himself one of the original members of the Association, is a native of and resident in this country.

At both of our former meetings held in Dublin, in 1835 and 1857 respectively, while greatly indebted to the liberal hospitality of the citizens at large, we were, as we now are, under especial obligations to the authorities of Trinity College for placing at our disposal buildings, not only unusually spacious and convenient in themselves, but full of reminiscences calculated to awake the scientific sympathies of all who may be gathered in them. At both of those former Dublin meetings the venerable name of Lloyd figured at our head; and if long-established custom had not seemed to preclude it, I could on many accounts have wished that we had met for a third time under the same name. And although other distinguished men, such as Dr. Robinson, Professors Stokes, Tyndall, and Andrews, are similarly disqualified by having already passed the presidential chair, while others again, such as Sir W. R. Hamilton, Dr. M'Cullagh, and Prof. Jukes, are permanently lost to our ranks; still we should not have had far to seek, had we looked for a president in this fertile island itself. But as every one connected with the place of meeting partakes of the character of host towards ourselves as guests, it has been thought by our oldest and most experienced members that we should better respond to an invitation by bringing with us a president to speak as our representative than by seeking one on the spot; and we may always hope on subsequent occasions that some of our present hosts may respond to a similar call.

But leaving our past history, which will form a theme more appropriate to our jubilee meeting in 1881 at the ancient city of York, I will ask your attention to a few particulars of our actual operations.

Its Relation to other Societies.

Time was when the Royal Societies of London and Edinburgh and the Royal Irish Academy were the only representative bodies of British science and the only receptacles of memoirs relating thereto. But latterly, the division of labour, so general in industrial life, has operated in giving rise to special societies, such as the Astronomical, the Linnæan, the Chemical, the Geological, the Geographical, the Statistical, the Mathematical, the Physical, and many others. To both the earlier or more general, and the later or more special societies alike, the British Association shows resemblance and affinity. We are general in our comprehensiveness; we are special in our sectional arrangement; and in this respect we offer not only a counterpart, but to some extent a counterpoise, to the general tendency to subdivision in science. Further still, while maintaining in their integrity all the elements of a strictly scientific body, we also include, in our character of a microcosm, and under our more social aspect, a certain freedom of treatment, and interaction of our various

branches, which is scarcely possible among separate and independent societies.

The general business of our meetings consists first, in receiving and discussing communications upon scientific subjects at the various sections into which our body is divided, with discussions thereon; secondly, in distributing, under the advice of our Committee of Recommendations, the funds arising from the subscriptions of members and associates; and thirdly, in electing a council upon whom devolves the conduct of our affairs until the next meeting.

The communications to the sections are of two kinds, viz., papers from individuals, and reports from committees.

Papers for the Sections, &c.

As to the subject matter of the papers, nothing which falls within the range of natural knowledge as partitioned among our sections, can be considered foreign to the purposes of the Association; and even many applications of science, when viewed in reference to their scientific basis, may properly find a place in our proceedings. So numerous, however, are the topics herein comprised, so easy the transition beyond these limits, that it has been thought necessary to confine ourselves within this range, lest the introduction of other matters, however interesting to individual members, should lead to the sacrifice of more important subjects. As to the form of the communications, while it is quite true that every scientific conclusion should be based upon substantial evidence, every theory complete before being submitted for final adoption, it is not the less desirable that even tentative conclusions and hypothetical principles, when supported by sufficient *primâ facie* evidence, and enunciated in such a manner as to be clearly apprehended, should find room for discussion at our sectional meetings. Considering, however, our limitations of time and the varied nature of our audience, it would seem not inappropriate to suspend, mentally if not materially, over the doors of our section rooms, the Frenchman's dictum, that no scientific theory "can be considered complete until it is so clear that it can be explained to the first man you meet in the street."

Special Reports.

Among the communications to the sections undoubtedly the most important, as a rule, are the Reports; that is to say, documents issuing from specially appointed committees, some of which have been recipients of the grants mentioned above. These reports are in the main of two kinds, first, accounts of observations carried on for a series of years, and intended as records of information on the special subjects; such, for instance, have been those made by the Kew Committee, by the Committees on Luminous Meteors, on British Rainfall, on the Speed of Steamships, on Underground Temperature, on the Exploration of Certain Geological Caverns, &c. These investigations, frequently originating in the energy and special qualifications of an individual, but conducted under the control of a committee, have in many cases been continued from year to year, until either the object has been fully attained or the matter has passed into the hands of other bodies, which have thus been led to recognise an inquiry into these subjects as part and parcel of their appropriate functions. The second class is one which is perhaps even more peculiar to the Association; viz., the reports on the progress and present state of some main topics of science. Among these may be instanced the early Reports on Astronomy, on Optics, on the Progress of Analysis; and later, those on Electrical Resistance and on Tides; that of Prof. G. G. Stokes on Double Refraction; that of Prof. H. J. Smith on the Theory of Numbers; that of Mr. Russell on Hyperelliptic Transcendents, and others. On this head Prof. Carey Foster, in his address to the Mathematical and Physical Section at our meeting last year, made some excellent recommendations, to which, however, I need not at present more particularly refer, as the result of them will be duly laid before the section in the form of the report from a committee to whom they were referred. It will be sufficient here to add that the wide extension of the sciences in almost every branch, and the consequent specialisation of the studies of each individual, have rendered the need for such reports more than ever pressing, and if the course of true science should still run smooth it is probable that the need will increase rather than diminish.

If time and space had permitted, I should have further particularised the committees, occasionally appointed, on subjects connected with education. But I must leave this theme for some future president, and content myself with pointing out that the British Association alone among scientific societies concerns itself directly with these questions, and is open to appeals for counsel and support from the great teaching body of the country.

Grants.

One of the principal methods by which this Association materially promotes the advancement of science, and consequently one of its most important functions, consists in grants of money from its own income in aid of special scientific researches. The total amount so laid out during the forty-seven years of our existence has been no less than 44,000*l.*; and the average during the last ten years has been 1,450*l.* per annum. These sums have not only been in the main wisely voted and usefully expended, but they have been themselves productive of much additional voluntary expenditure of both time and money on the part of those to whom the grants have been entrusted. The results have come back to the Association in the form of papers and reports, many of which have been printed in our volumes. By this appropriation of a large portion of its funds the Association has to some extent anticipated, nay, even it may have partly inspired the ideas now so much discussed, of the endowment of research. And whether the aspirations of those who advocate such endowment be ever fully realised or not, there can, I think, be no doubt whatever that the Association in the mattter of these grants has afforded a most powerful stimulus to original research and discovery.

Regarded from another point of view these grants, together with others to be hereafter mentioned, present a strong similarity to that useful institution the Professoriate Extraordinary of Germany, to which there are no foundations exactly corresponding in this country. For beside their more direct educational purpose, these professorships are intended, like our own grants, to afford to special individuals an opportunity of following out the special work for which they have previously proved themselves competent. And in this respect the British Association may be regarded as supplying, to the extent of its means, an elasticity which is wanting in our own universities.

Other Funds.

Besides the funds which through your support are at the disposal of the British Association there are, as is well known to many here present, other funds of more or less similar character at the disposal, or subject to the recommendations, of the Royal Society. There is the Donation Fund, the property of the Society; the Government Grant of 1,000*l.* per annum, administered by the Society; and the Government Fund of 4,000*l.* per annum (an experiment for five years) to be distributed by the Science and Art Department, both for research itself and for the support of those engaged thereon, at the recommendation of a committee consisting mainly of Fellows of the Royal Society. To these might be added other funds in the hands of different scientific societies.

But although it must be admitted that the purposes of these various funds are not to be distinguished by any very simple line of demarcation, and that they may therefore occasionally appear to overlap one another, it may still, I think, be fairly maintained that this fact does not furnish any sufficient reason against their co-existence. There are many topics of research too minute in their range, too tentative in their present condition, to come fairly within the scope of the funds administered by the Royal Society. There are others, ample enough in their extent, and long enough in their necessary duration, to claim for their support a national grant, but which need to be actually set on foot or tried before they can fairly expect the recognition either of the public or of the government. To these categories others might be added; but the above-mentioned instances will perhaps suffice to show that even if larger and more permanent funds were devoted to the promotion of research than is the case at present, there would still be a field of activity open to the British Association as well as to other scientific bodies which may have funds at their disposal.

On the general question it is not difficult to offer strong arguments in favour of permanent national scientific institutions; nor is it difficult to picture to the mind an ideal future when Science and Art shall walk hand in hand together, led by a willing minister into the green pastures of the Endowment of Research.[1] But while allowing this to be no impossible a

[1] It is worth while to compare the following passage from Plato's "Republic," Book vii. (Jowett's translation):—
After plane geometry, we took solids in revolution instead of taking solids

future, we must still admit that there are other and less promising possibilities, which under existing circumstances cannot be altogether left out of our calculations. I am therefore, on the whole, inclined to think that, while not losing sight of larger schemes, the wisest policy, for the present at all events, and pending the experiment of the Government Fund, will be to confine our efforts to a careful selection of definite persons to carry out definite pieces of work; leaving to them the honour (or the onus if they so think it) of justifying from time to time a continuation of the confidence which the government or other supporting body may have once placed in them.

Continuance of British Association.

Passing from the proceedings to other features and functions of our body, it should be remembered that the continued existence of the Association must depend largely upon the support which it receives from its members and associates. Stinted in the funds so arising, its scientific effectiveness would be materially impaired; and deprived of them, its existence would be precarious. The amount at our disposal in each year will naturally vary with the population, with the accessibility, and with other circumstances of the place of meeting; there will be financially, as well as scientifically, good years and bad years. But we have in our invested capital a sum sufficient to tide over all probable fluctuations, and even to carry us efficiently through several years of financial famine, if ever such should occur. This seems to me sufficient; and we have therefore, I think, no need to increase our reserve, beyond perhaps the moderate addition which a prudent treasurer will always try to secure, against expenditure which often increases and rarely diminishes.

But however important this material support may be to our existence and well being, it is by no means all that is required. There is another factor which enters into the product, namely, the personal scientific support of our best men. It is, I think, not too much to say, that without their presence our meetings would fail in their chief and most important element, and had best be discontinued altogether. We make, it must be admitted, a demand of sensible magnitude in calling upon men who have been actively engaged during a great portion of the year, at a season when they may fairly look for relaxation, to attend a busy meeting, and to contribute to its proceedings; but unless a fair quota at least of our veterans, and a good muster of our younger men, put in their appearance, our gatherings will be to little purpose. There was a period within my own recollection when it was uncertain whether the then younger members of our scientific growth would cast in their lot with us or not, and when the fate of the Association depended very much upon their decision. They decided in our favour; they have since become presidents, lecturers, and other functionaries of our body; with what result it is for you to judge.

Of the advantages which may possibly accrue to the locality in which our meetings are held, it is not for us to speak; but it is always a ground for sincere satisfaction to learn that our presence has been of any use in stimulating an interest, or in promoting local efforts, in the direction of science.

The Council.

The functions of the British Association do not, however, terminate with the meeting itself. Beside the special committees already mentioned, there remains a very important body, elected by the General Committee, viz., the Council, which assembles at the office in London from time to time as occasion requires. To this body belongs the duty of proposing a president, of preparing for the approval of the General Committee the list of vice-presidents and sectional officers, the selection of evening lecturers, and other arrangements for the coming meeting.

At the present time another class of questions occupies a good deal of the attention of the Council. In the first generation of the Association, and during the period of unwritten, but not yet traditional, law, questions relating to our own organisation or procedure either "settled themselves," or were wisely left to the discretionary powers of those who had taken part in our proceedings during the early years of our existence. These and other kindred subjects now require more careful formularisation and more deliberate sanction. And it is on the shoulders of the Council that the weight of these matters in general falls. These facts deserve especial mention on the present occasion, because one part of our business at the close of this meeting will be to bid farewell officially to one who has served us as assistant secretary so long and so assiduously that he has latterly become our main repertory of information, and our Mentor upon questions of precedent and procedure. The post hitherto held by Mr. Griffith (for it is to him that I allude) will doubtless be well filled by the able and energetic member who has been nominated in his place; but I doubt not that even he will be glad for some time to come to draw largely upon the knowledge and experience of his predecessor.

But, beside matters of internal arrangement and organisation, the duties of the Council comprise a variety of scientific subjects referred to them by the General Committee, at the instance of the Committee of Recommendations, for deliberation and occasionally for action. With the increasing activity of our body in general, and more particularly with that of our various officers, these duties have of late years become more varied and onerous than formerly; nor is it to be wished that they should diminish in either variety or extent.

Once more, questions beyond our own constitution, and even beyond the scope of our own immediate action, such as education, legislation affecting either the promotion or the applications of science to industrial and social life, which have suggested themselves at our meetings, and received the preliminary sanction of our Committee of Recommendations, are frequently referred to our Council. These, and others which it is unnecessary to particularise, whether discussed in full council or in committees specially appointed by that body, render the duties of our councillors as onerous as they are important.

Its Relations with Government.

While the government has at all times, but in a more marked manner of late years, recognised the Royal Society of London, with representatives from the sister societies of Dublin and of Edinburgh, as the body to which it should look for counsel and advice upon scientific questions, it has still never shown itself indisposed to receive and entertain any well-considered recommendation from the British Association. Two special causes have in all probability contributed largely to this result. First, the variety of elements comprised by the Association, on account of which its recommendations imply a more general concurrence of scientific opinion than those of any other scientific body. Secondly, the peculiar fact that our period of maximum activity coincides with that of minimum activity of other scientific bodies is often of the highest importance. At the very time when the other bodies are least able, we are most able, to give deliberate consideration, and formal sanction, to recommendations whether in the form of applications to government or otherwise which may arise. In many of these time is an element so essential, that it is not too much to say that without the intervention of the British Association many opportunities for the advancement of science, especially at the seasons in question, might have been lost. The government has, moreover, formally recognised our scientific existence by appointing our president for the time being a member of the Government Fund Committee; and the public has added its testimony to our importance and utility by imposing upon our president and officers a variety of duties, among which are conspicuous those which arise out of its very liberal exercise of civic and other hospitality.

Presidential Addresses

Of the nature and functions of the presidential address this is perhaps neither the time nor the place to speak; but if I might for a moment forget the purpose for which we are now assembled, I would take the opportunity of reminding those who have not attended many of our former meetings, that our annual volumes contain a long series of addresses on the progress of science, from a number of our most eminent men, to which there is perhaps no parallel elsewhere. These addresses are perhaps as remarkable for their variety in mode of treatment as

in themselves; whereas after the second dimension the third, which is concerned with cubes and dimensions of depth, ought to have been followed.

It is true, Socrates; but these subjects seem to be as yet hardly explored.

Why, yes, I said, and for two reasons; in the first place, no government patronises them, which leads to a want of energy in the study of them, and they are difficult; in the second place, students cannot learn them unless they have a teacher. But then a teacher is hardly to be found, and even if one could be found, as matters now stand the students of these subjects, who are very conceited, would not mind him; that, however, would be otherwise if the whole state patronised and honoured them, then they would listen, and there would be continuous and earnest search, and discoveries would be made; since even now, disregarded as they are by the world, and maimed of their fair proportions, and although none of their votaries can tell the use of them, still these studies force their way by their natural charm, and very likely they may emerge into light.

for the value of their subject-matter. Some of our presidents, and especially those who officiated in the earlier days of our existence, have passed in review the various branches of science, and have noted the progress made in each during the current year. But, as the various sciences have demanded more and more special treatment on the part of those who seriously pursue them, so have the cases of individuals who can of their own knowledge give anything approaching to a general review become more and more rare. To this may be added the fact that although no year is so barren as to fail in affording sufficient crop for a strictly scientific budget, or for a detailed report of progress in research, yet one year is more fertile than another in growths of sufficient prominence to arrest the attention of the general public, and to supply topics suitable for the address. On these accounts, apparently, such a presidential survey has ceased to be annual, and has dropped into an intermittence of longer period. Some presidents have made a scientific principle, such as the time-element in natural phenomena, or continuity, or natural selection, the theme of their discourse, and have gathered illustrations from various branches of knowledge. Others again, taking their own special subject as a fundamental note, and thence modulating into other kindred keys, have borne testimony to the fact that no subject is so special as to be devoid of bearing or of influence on many others. Some have described the successive stages of even a single but important investigation; and while tracing the growth of that particular item, and of the ideas involved in it, have incidentally shown to the outer world what manner of business a serious investigation is. But there is happily no pattern or precedent which the president is bound to follow; both in range of subject-matter and in mode of treatment each has exercised his undoubted right of taking an independent line. And it can hardly be doubted that a judicious exercise of this freedom has contributed more than anything else to sustain the interest of a series of annual discourses extending now over nearly half a century.

The nature of the subjects which may fairly come within the scope of such a discourse has of late been much discussed; and the question is one upon which every one is of course entitled to form his own judgment; but lest there should be any misapprehension as to how far it concerns us in our corporate capacity, it will be well to remind my hearers that as, on the one hand, there is no discussion on the presidential address, and the members as a body express no opinion upon it, so, on the other, the Association cannot fairly be considered as in any way committed to its tenour or conclusions. Whether this immunity from comment and reply be really on the whole so advantageous to the president as might be supposed need not here be discussed, but suffice it to say that the case of an audience assembled to listen without discussion finds a parallel elsewhere, and in the parallel case it is not always considered that the result is altogether either advantageous to the speaker or conducive to excellence in the discourse.

Their Range of Subjects.

But, apart from this, the question of a limitation of range in the subject-matter for the presidential address is not quite so simple as may at first sight appear. It must, in fact, be borne in mind that, while on the one hand knowledge is distinct from opinion, from feeling, and from all other modes of subjective impression, still the limits of knowledge are at all times expanding, and the boundaries of the known and the unknown are never rigid or permanently fixed. That which in time past or present has belonged to one category, may in time future belong to the other. Our ignorance consists partly in ignorance of actual facts, and partly also in ignorance of the possible range of ascertainable fact. If we could lay down beforehand precise limits of possible knowledge, the problem of physical science would be already half solved. But the question to which the scientific explorer has often to address himself is, not merely whether he is able to solve this or that problem, but whether he can so far unravel the tangled threads of the matter with which he has had to deal as to weave them into a definite problem at all. He is not like a candidate at an examination with a precise set of questions placed before him; he must first himself act the part of the examiner and select questions from the repertory of nature, and upon them found others, which in some sense are capable of definite solution. If his eye seem dim, he must look steadfastly and with hope into the misty vision, until the very clouds wreath themselves into definite forms. If his ear seem dull, he must listen patiently and with sympathetic trust to the intricate whisperings of nature—the goddess, as she has been called, of a hundred voices—until here and there he can pick out a few simple notes to which his own powers can resound. If, then, at a moment when he finds himself placed on a pinnacle from which he is called upon to take a perspective survey of the range of science, and to tell us what he can see from his vantage ground; if, at such a moment, after straining his gaze to the very verge of the horizon, and after describing the most distant of well-defined objects, he should give utterance also to some of the subjective impressions which he is conscious of receiving from regions beyond; if he should depict possibilities which seem opening to his view; if he should explain why he thinks this a mere blind alley and that an open path; then the fault and the loss would be alike ours if we refused to listen calmly, and temperately to form our own judgment on what we hear; then assuredly it is we who would be committing the error of confounding matters of fact and matters of opinion, if we failed to discriminate between the various elements contained in such a discourse, and assumed that they had all been put on the same footing.

Presidential Difficulties.

But to whatever decision we may each come on these controverted points, one thing appears clear from a retrospect of past experience; viz., that first or last, either at the outset in his choice of subject or in the conclusions ultimately drawn therefrom, the president, according to his own account at least, finds himself on every occasion in a position of "exceptional, or more than usual difficulty." And your present representative, like his predecessors, feels himself this moment in a similar predicament. The reason which he now offers is that the branch of science which he represents is one whose lines of advance, viewed from a mathematician's own point of view, offer so few points of contact with the ordinary experiences of life or modes of thought, that any account of its actual progress which he might have attempted must have failed in the first requisite of an address, namely, that of being intelligible.

View of Mathematics here taken.

Now if this esoteric view had been the only aspect of the subject which he could present to his hearers, he might well have given up the attempt in despair. But although in its technical character mathematical science suffers the inconveniences, while it enjoys the dignity, of its Olympian position; still in a less formal garb, or in disguise, if you are pleased so to call it, it is found present at many an unexpected turn; and although some of us may never have learnt its special language, not a few have, all through our scientific life, and even in almost every accurate utterance, like Molière's well-known character, been talking mathematics without knowing it. It is, moreover, a fact not to be overlooked that the appearance of isolation, so conspicuous in mathematics, appertains in a greater or less degree to all other sciences, and perhaps also to all pursuits in life. In its highest flight each soars to a distance from its fellows. Each is pursued alone for its own sake, and without reference to its connection with, or its application to, any other subject. The pioneer and the advanced guard are of necessity separated from the main body, and in this respect mathematics does not materially differ from its neighbours. And therefore as the solitariness of mathematics has been a frequent theme of discourse, it may be not altogether unprofitable to dwell for a short time upon the other side of the question, and to inquire whether there be not points of contact in method or in subject-matter between mathematics and the outer world which have been frequently overlooked; whether its lines do not in some cases run parallel to those of other occupations and purposes of life; and lastly, whether we may not hope for some change in the attitude too often assumed towards it by the representatives of other branches of knowledge and of mental activity.

In his Preface to the "Principia," Newton gives expression to some general ideas which may well serve as the key-note for all future utterances on the relation of mathematics to natural, including also therein what are commonly called artificial, phenomena.

Newton's Preface.

"The ancients divided mechanics into two parts, rational and practical; and since artisans often work inaccurately, it came to pass that mechanics and geometry were distinguished in this way—that everything accurate was referred to geometry, and everything inaccurate to mechanics. But the inaccuracies appertain to the artisan and not to the art, and geometry itself has its

foundation in mechanical practice, and is in fact nothing else than that part of universal mechanics which accurately lays down and demostrates the art of measuring."[1] He next explains that rational mechanics is the science of motion resulting from forces, and adds, "The whole difficulty of philosophy seems to me to lie in investigating the forces of nature from the phenomena of motion; and in demonstrating that from these forces other phenomena will ensue." Then, after stating the problems of which he has treated in the work itself, he says: "I would that all other natural phenomena might similarly be deduced from mechanical principles. For many things move me to suspect that everything depends upon certain forces in virtue of which the particles of bodies, through forces not yet understood, are either impelled together so as to cohere in regular figures, or are repelled and recede from one another."

Burrowes' Remarks.

Newton's views, then, are clear; he regards mathematics not as a method independent of, though applicable to, various subjects, but as itself the higher side or aspect of the subjects themselves; and it would be little more than a translation of his notions into other language, little more than a paraphrase of his own words, if we were to describe the mathematical as one aspect of the material world itself, apart from which all other aspects are but incomplete sketches, and however accurate after their own kind, are still liable to the imperfections of the inaccurate artificer. Mr. Burrowes, in his Preface to the first volume of the *Transactions* of the Royal Irish Academy, has carried out the same argument, approaching it from the other side; "No one science," he says, "is so little connected with the rest as not to afford many principles whose use may extend considerably beyond the science to which they primarily belong, and no proposition is so purely theoretical as to be incapable of being applied to practical purposes. There is no apparent connection between duration and the cycloidal arch, the properties of which have furnished us with the best method of measuring time; and he who has made himself master of the nature and affections of the logarithmic curve has advanced considerably towards ascertaining the proportionable density of the air at various distances from the earth. The researches of the mathematician are the only sure ground on which we can reason from experiments; and how far experimental science may assist commercial interests is evinced by the success of manufactures in countries where the hand of the artificer has taken its direction from the philosopher. Every manufacture is in reality but a chemical process, and the machinery requisite for carrying it on but the right application of certain propositions in rational mechanics." So far your academician. Every subject, therefore, whether in its usual acceptation scientific or otherwise, may have a mathematical aspect; as soon, in fact, as it becomes a matter of strict measurement, or of numerical statement, so soon does it enter upon a mathematical phase. This phase may, or it may not, be a prelude to another in which the laws of the subject are expressed in algebraical formulæ or represented by geometrical figures. But the real gist of the business does not always lie in the mode of expression; and the fascination of the formulæ or other mathematical paraphernalia may after all be little more than that of a theatrical transformation scene. The process of reducing to formulæ is really one of abstraction, the results of which are not always wholly on the side of gain; in fact, through the process itself the subject may lose in one respect even more than it gains in another. But long before such abstraction is completely attained, and even in cases where it is never attained at all, a subject may to all intents and purposes become mathematical. It is not so much elaborate calculations or abstruse processes which characterise this phase, as the principles of precision, of exactness, and of proportion. But these are principles with which no true knowledge can entirely dispense. If it be the general scientific spirit which at the outset moves upon the face of the waters, and out of the unknown depth brings forth light and living forms; it is no less the mathematical spirit which breathes the breath of life into what would otherwise have ever remained mere dry bones of fact, which re-unites the scattered limbs and re-creates from them a new and organic whole.

And as a matter of fact, in the words used by Prof. Jellett at our meeting at Belfast, viz., "Not only are we applying our methods to many sciences already recognised as belonging to the legitimate province of mathematics, but we are learning to apply the same instrument to sciences hitherto wholly or partially independent of its authority. Physical science is learning more and more every day to see in the phenomena of nature modifications of that one phenomenon (namely, motion) which is peculiarly under the power of mathematics." Echoes are these, far off and faint perhaps, but still true echoes, in answer to Newton's wish that all these phenomena may some day "be deduced from mechanical principles."

[1] Compare with this the latter part of Plato's "Philebus" on knowledge and the handicraft arts; also Prof. Jowett's Introduction thereto.

Mathematics, Literature, and Art.

If, turning from this aspect of the subject, it were my purpose to enumerate how the same tendency has evinced itself in the arts, unconsciously it may be to the artists themselves, I might call as witnesses each one in turn with full reliance on the testimony which they would bear. And, having more special reference to mathematics, I might confidently point to the accuracy of measurement, to the truth of curve, which, according to modern investigation, is the key to the perfection of classic art. I might triumphantly cite not only the architects of all ages, whose art so manifestly rests upon mathematical principles, but I might cite also the literary as well as the artistic remains of the great artists of the Cinquecento, both painters and sculptors, in evidence of the geometry and the mechanics which, having been laid at the foundation, appear to have found their way upwards through the superstructure of their works.[1] And in a less ambitious sphere, but nearer to ourselves in both time and place, I might point with satisfaction to the great school of English constructors of the eighteenth century in the domestic arts; and remind you that not only the engineer and the architect, but even the cabinet-makers, devoted half the space of their books to perspective and to the principles whereby solid figures may be delineated on paper, or what is now termed descriptive geometry.[2]

Nor perhaps would the sciences which concern themselves with reasoning and speech, nor the kindred art of music, nor even literature itself, if thoroughly probed, offer fewer points of dependence upon the science of which I am speaking. What, in fact, is logic but that part of universal reasoning; grammar but that part of universal speech: harmony and counterpoint but that part of universal music, "which accurately lays down," and demonstrates (so far as demonstration is possible) precise methods appertaining to each of these arts? And I might even appeal to the common consent which speaks of the mathematical as the pattern form of reasoning and model of a precise style.

Taking, then, precision and exactness as the characteristics which distinguish the mathematical phase of a subject, we are naturally led to expect that the approach to such a phase will be indicated by increasing application of the principle of measurement, and by the importance which is attached to numerical results. And this very necessary condition for progress may, I think, be fairly described as one of the main features of scientific advance in the present day.

Measurements in Physics.

If it were my purpose, by descending into the arena of special sciences, to show how the most various investigations alike tend to issue in measurement, and to that extent to assume a mathematical phase, I should be embarrassed by the abundance of instances which might be adduced. I will therefore confine myself to a passing notice of a very few, selecting those which exemplify not only the general tendency, but also the special character of the measurements now particularly required, viz., that of minuteness, and the indirect method by which alone we can at present hope to approach them. An object having a diameter of an 80,000th of an inch is perhaps the smallest of which the microscope could give any well-defined representation; and it is improbable that one of 120,000th of an inch could be singly discerned with the highest powers at our command.[3] But the solar beams and the electric light reveal to us the presence of bodies far smaller than these. And, in the absence of any means of observing them singly, Prof. Tyndall has suggested a scale of these minute objects in terms of the lengths of luminiferous waves. To this he was led, not by any attempt at individual measurement, but by taking account of them in the

aggregate, and observing the tints which they scatter laterally when clustered in the form of actinic clouds.[1] The small bodies with which experimental science has recently come into contact are not confined to gaseous molecules, but comprise also complete organisms; and the same philosopher has made a profound study of the momentous influence exerted by these minute organisms in the economy of life.[2] And if, in view of their specific effects, whether deleterious or other, on human life, any qualitative classification, or quantitative estimate be ever possible, it seems that it must be effected by some such method as that indicated above.

Again, to enumerate a few more instances of the measurement of minute quantities, there are the average distances of molecules from one another in various gases and at various pressures; the length of their free path, or range open for their motion without coming into collision; there are movements causing the pressures and differences of pressure under which Mr. Crookes' radiometers execute their wonderful revolutions.[3] There are the excursions of the air while transmitting notes of high pitch, which through the researches of Lord Rayleigh appear to be of a diminutiveness altogether unexpected.[4] There are the molecular actions brought into play in the remarkable experiments by Dr. Ker,[5] who has succeeded, where even Faraday failed, in effecting a visible rotation of the plane of polarisation of light in its passage through electrified dielectrics, and on its reflection at the surface of a magnet. To take one more instance, which must be present to the minds of us all, there are the infinitesimal ripples of the vibrating plate in Mr. Graham Bell's most marvellous invention. Of the nodes and ventral segments in the plate of the telephone which actually converts sound into electricity and electricity into sound, we can at present form no conception. All that can now be said is that the most perfect specimens of Chladni's sand figures on a vibrating plate, or of Kundt's lycopodium heaps in a musical tube,[6] or even Mr. Sedley Taylor's more delicate vortices in the films of the phoneidoscope,[7] are rough and sketchy compared with these. For notwithstanding the fact that in the movements of the telephone-plate we have actually in our hand the solution of that old world-problem the construction of a speaking-machine, yet the characters in which that solution is expressed are too small for our powers of decipherment. In movements such as these we seem to lose sight of the distinction, or perhaps we have unconsciously passed the boundary between massive and molecular motion.[8]

Through the phonograph [9] we have not only a transformation, but a permanent and tangible record of the mechanism of speech. But the differences upon which articulation (apart from loudness, pitch, and quality) depends, appear from the experiments of Fleeming Jenkin and of others, to be of microscopic size. The microphone affords another instance [10] of the unexpected value of minute variations,—in this case of electric currents; and it is remarkable that the gist of the instrument seems to lie in obtaining and perfecting that which electricians have hitherto most scrupulously avoided, viz., loose contact.

Once more, Mr. De La Rue has brought forward as one of the results [11] derived from his stupendous battery of 10,000 cells, strong evidence for supposing that a voltaic discharge, even when apparently continuous, may still be an intermittent phenomenon; but all that is known of the period of such intermittence is, that it must recur at exceedingly short intervals. And in connection with this subject, it may be added that, whatever be the ultimate explanation of the strange stratification which the voltaic discharge undergoes in rarefied gases, it is clear that the alternate disposition of light and darkness must be dependent on some periodic distribution in space or sequence in time which can at present be dealt with only in a very general way. In the exhausted column we have a vehicle for electricity not constant like an ordinary conductor, but itself modified by the passage of the discharge, and perhaps subject to laws differing materially from those which it obeys at atmospheric pressure. It may also be that some of the features accompanying stratification form a magnified image of phenomena belonging to disruptive discharges in general; and that consequently so far from expecting among the known facts of the latter any clue to an explanation of the former, we must hope ultimately to find in the former an elucidation of what is at present obscure in the latter. A prudent philosopher usually avoids hazarding any forecast of the practical application of a purely scientific research. But it would seem that the configuration of these striæ might some day prove a very delicate means of estimating low pressures, and perhaps also for effecting some electrical measurements.

Now, it is a curious fact that almost the only small quantities of which we have as yet any actual measurements are the wave-lengths of light; and that all others, excepting so far as they can be deduced from these, await future determination. In the mean time, when unable to approach these small quantities individually, the method to which we are obliged to have recourse is, as indicated above, that of averages, whereby, disregarding the circumstances of each particular case, we calculate the average size, the average velocity, the average direction, &c., of a large number of instances.[1] But although this method is based upon experience, and leads to results which may be accepted as substantially true; although it may be applicable to any finite interval of time, or over any finite area of space (that is, for all practical purposes of life) there is no evidence to show that it is so when the dimensions of interval or of area are indefinitely diminished. The truth is that the simplicity of nature which we at present grasp is really the result of infinite complexity; and that below the uniformity there underlies a diversity whose depths we have not yet probed, and whose secret places are still beyond our reach.

The present is not an occasion for multiplying illustrations, but I can hardly omit a passing allusion to one all-important instance of the application of the statistical method. Without its aid social life, or the History of Life and Death, could not be conceived at all, or only in the most superficial manner. Without it we could never attain to any clear ideas of the condition of the poor, we could never hope for any solid amelioration of their condition or prospects. Without its aid, sanitary measures, and even medicine, would be powerless. Without it, the politician and the philanthropist would alike be wandering over a trackless desert.

Mathematical Methods and other Subjects.

It is, however, not so much from the side of science at large as from that of mathematics itself, that I desire to speak. I wish from the latter point of view to indicate connections between mathematics and other subjects, to prove that hers is not after all such a far-off region, nor so undecipherable an alphabet, and to show that even at unlikely spots we may trace under-currents of thought which, having issued from a common source, fertilise alike the mathematical and the non-mathematical world.

Having this in view, I propose to make the subject of special remark some processes peculiar to modern mathematics; and, partly with the object of incidentally removing some current misapprehensions, I have selected for examination three methods in respect of which mathematicians are often thought to have exceeded all reasonable limits of speculation, and to have adopted for unknown purposes an unknown tongue.

And it will be my endeavour to show not only that in these very cases our science has not outstepped its own legitimate range, but that even art and literature have unconsciously employed methods similar in principle. The three methods in question are first, that of imaginary quantities; secondly that of manifold space, and thirdly, that of geometry not according to Euclid.

Imaginaries.

First it is objected that, abandoning the more cautious methods of ancient mathematicians, we have admitted into our formulæ quantities which by our own showing, and even in our own nomenclature, are imaginary or impossible; nay, more, that out of them we have formed a variety of new algebras to which there is no counterpart whatever in reality, but from which we claim to arrive at possible and certain results.

On this head it is in Dublin, if anywhere, that I may be per-

mitted to speak. For to the fertile imagination of the late Astronomer-Royal for Ireland we are indebted for that marvellous calculus of quaternions, which is only now beginning to be fully understood, and which has not yet received all the applications of which it is doubtless capable. And even although this calculus be not coextensive with another (the Ausdehnungslehre of Grassmann)[1] which almost simultaneously germinated on the Continent, nor with ideas more recently developed in America (Pierce's "Linear Associative Algebras");[2] yet it must always hold its position as an original discovery and as a representative of one of the two great groups of generalised algebras (viz., those the squares of whose units are respectively negative unity and zero) the common origin of which must still be marked on our intellectual map as an unknown region. Well do I recollect how in its early days we used to handle the method as a magician's page might try to wield his master's wand, trembling as it were between hope and fear, and hardly knowing whether to trust our own results until they had been submitted to the present and ever ready counsel of Sir W. R. Hamilton himself.

To fix our ideas, consider the measurement of a line, or the reckoning of time, or the performance of any mathematical operation. A line may be measured in one direction or in the opposite; time may be reckoned forward or backward; an operation may be performed or be reversed, it may be done or may be undone; and if having once reversed any of these processes we reverse it a second time, we shall find that we have come back to the original direction of measurement or reckoning, or to the original kind of operation.

Suppose, however, that at some stage of a calculation our formulæ indicate an alteration in the mode of measuremen such that if the alteration be repeated, a condition of things ntot the same as, but the reverse of the original, will be produced. Or suppose that, at a certain stage, our transformations indicate that time is to be reckoned in some manner different from future or past, but still in a way having definite algebraical connection with time which is gone and time which is to come.[3] It is clear that in actual experience there is no process to which such measurements correspond. Time has no meaning except as future or past; and the present is but the meeting point of the two. Or, once more, suppose that we are gravely told that all circles pass through the same two imaginary points at an infinite distance, and that every line drawn through one of these points is perpendicular to itself. On hearing the statement we shall probably whisper, with a smile or a sigh, that we hope it is not true, but that in any case it is a long way off, and perhaps, after all, it does not very much signify. If, however, we are not satisfied to dismiss the question on these terms, the mathematician himself must admit that we have here reached a definite point of issue. Our science must either give a rational account of the dilemma, or yield the position as no longer tenable.

Explanation of them.

Special modes of explaining this anomalous state of things have occurred to mathematicians. But, omitting details as unsuited to the present occasion, it will, I think, be sufficient to point out in general terms that a solution of the difficulty is to be found in the fact that the formulæ which give rise to these results are more comprehensive than the signification which has been given to them; and when we pass out of the condition of things first contemplated they cannot (as it is obvious they ought not) give us any results intelligible on that basis. But it does not therefore by any means follow that upon a more enlarged basis the formulæ are incapable of interpretation; on the contrary, the difficulty at which we have arrived indicates that there must be some more comprehensive statement of the problem which will include cases impossible in the more limited, but possible in the wider view of the subject.

[2] "Linear Associative Algebra," by Benjamin Pierce, Washington City, 1870.

[3] Sir W. Thomson, *Cambridge Mathematical Journal*, vol. iii. p. 174. Jevons' "Principles of Science," vol. ii. p. 438. But an explanation of the difficulty seems to me to be found in the fact that the problem, as stated, is one of the conduction of heat, and that the "impossibility" which attaches itself to the expression for the "time" merely means that previous to a certain epoch the conditions which gave rise to the phenomena were not those of conduction, but those of some other action of heat. If, therefore, we desire to comprise the phenomena of the earlier as well as of the later period in one problem, we must find some more general statement; viz., that of physical conditions which at the critical epoch will issue in a case of conduction. I think that Prof. Clifford has somewhere given a similar explanation.

A very simple instance will illustrate the matter. If from a point outside a circle we draw a straight line to touch the curve, the distance between the starting point and the point of contact has certain geometrical properties. If the starting point be shifted nearer and nearer to the circle the distance in question becomes shorter, and ultimately vanishes. But as soon as the point passes to the interior of the circle the notion of a tangent and distance to the point of contact cease to have any meaning; and the same anomalous condition of things prevails as long as the point remains in the interior. But if the point be shifted still further until it emerges on the other side, the tangent and its properties resume their reality; and are as intelligible as before. Now the process whereby we have passed from the possible to the impossible, and again repassed to the possible (namely the shifting of the starting point) is a perfectly continuous one, while the conditions of the problem as stated above have abruptly changed. If, however, we replace the idea of a line touching by that of a line cutting the circle, and the distance of the point of contact by the distances at which the line is intercepted by the curve, it will easily be seen that the latter includes the former as a limiting case, when the cutting line is turned about the starting point until it coincides with the tangent itself. And further, that the two intercepts have a perfectly distinct and intelligible meaning whether the point be outside or inside the area. The only difference is that in the first case the intercepts are measured in the same direction; in the latter in opposite directions.

The foregoing instance has shown one purpose which these imaginaries may serve, viz., as marks indicating a limit to a particular condition of things, to the application of a particular law, or pointing out a stage where a more comprehensive law is required. To attain to such a law we must, as in the instance of the circle and tangent, reconsider our statement of the problem; we must go back to the principle from which we set out, and ascertain whether it may not be modified or enlarged. And even if in any particular investigation, wherein imaginaries have occurred, the most comprehensive statement of the problem of which we are at present capable fails to give an actual representation of these quantities; if they must for the present be relegated to the category of imaginaries; it still does not follow that we may not at some future time find a law which will endow them with reality, nor that in the meantime we need hesitate to employ them, in accordance with the great principle of continuity, for bringing out correct results.

Illustration from Art and Literature.

If, moreover, both in geometry and in algebra we occasionally make use of points or of quantities which from our present outlook have no real existence, which can neither be delineated in space of which we have experience, nor measured by scale as we count measurement; if these imaginaries, as they are termed, are called up by legitimate processes of our science; if they serve the purpose not merely of suggesting ideas, but of actually conducting us to practical conclusions; if all this be true in abstract science, I may perhaps be allowed to point out, at all events in illustration, that in art unreal forms are frequently used for suggesting ideas, for conveying a meaning for which no others seem to be suitable or adequate. Are not forms unknown to biology, situations incompatible with gravitation, positions which challenge not merely the stability but the very possibility of equilibrium—are not these the very means to which the artist often has recourse in order to convey his meaning and to fulfil his mission? Who that has ever revelled in the ornamentation of the Renaissance, in the extraordinary transitions from the animal to the vegetable, from faunic to floral forms, and from these again to almost purely geometric curves, who has not felt that these imaginaries have a claim to recognition very similar to that of their congeners in mathematics? How is it that the grotesque paintings of the middle ages, the fantastic sculpture of remote nations, and even the rude art of the prehistoric past, still impress us, and have an interest over and above their antiquarian value; unless it be that they are symbols which, although hard of interpretation when taken alone, are yet capable from a more comprehensive point of view of leading us mentally to something beyond themselves, and to truths which, although reached through them, have a reality scarcely to be attributed to their outward forms?

Again, if we turn from art to letters, truth to nature and to fact is undoubtedly a characteristic of sterling literature; and yet in the delineation of outward nature itself, still more in that

of feelings and affections, of the secret springs of character and motives of conduct, it frequently happens that the writer is driven to imagery, to an analogy, or even to a paradox, in order to give utterance to that of which there is no direct counterpart in recognised speech. And yet which of us cannot find a meaning for these literary figures, an inward response, to imaginative poetry, to social fiction, or even to those tales of giant and fairyland written, it is supposed, only for the nursery or schoolroom? But in order thus to reanimate these things with a meaning beyond that of the mere words, have we not to reconsider our first position, to enlarge the ideas with which we started; have we not to cast about for something which is common to the idea conveyed and to the subject actually described, and to seek for the sympathetic spring which underlies both; have we not, like the mathematician, to go back as it were to some first principles, or as it is pleasanter to describe it, to become again as a little child?

Manifold Space.

Passing to the second of the three methods, viz., that of manifold space, it may first be remarked that our whole experience of space is in three dimensions, viz., of that which has length, breadth, and thickness; and if for certain purposes we restrict our ideas to two dimensions as in plane geometry, or to one dimension as in the division of a straight line, we do this only by consciously and of deliberate purpose setting aside, but not annihilating, the remaining one or two dimensions. Negation, as Hegel has justly remarked, implies that which is negatived, or, as he expresses it, affirms the opposite. It is by abstraction from previous experience, by a limitation of its results, and not by any independent process, that we arrive at the idea of space whose dimensions are less than three.

It is doubtless on this account that problems in plane geometry which, although capable of solution on their own account, become much more intelligible, more easy of extension, if viewed in connection with solid space, and as special cases of corresponding problems in solid geometry. So eminently is this the case that the very language of the more general method often leads us almost intuitively to conclusions which from the more restricted point of view require long and laborious proof. Such a change in the base of operations has, in fact, been successfully made in geometry of two dimensions, and although we have not the same experimental data for the further steps, yet neither the modes of reasoning, nor the validity of its conclusions, are in any way affected by applying an analogous mental process to geometry of three dimensions, and by regarding figures in space of three dimensions as sections of figures in space of four in the same way that figures in plano are sometimes considered as sections of figures in solid space. The addition of a fourth dimension to space not only extends the actual properties of geometrical figures, but it also adds new properties which are often useful for the purposes of transformation or of proof. Thus it has recently been shown that in four dimensions a closed material shell could be turned inside out[1] by simple flexure, without either stretching or tearing,[2] and that in such a space it is impossible to tie a knot.

Again, the solution of problems in geometry is often effected by means of algebra: and as three measurements, or co-ordinates as they are called, determine the position of a point in space, so do three letters or measurable quantities serve for the same purpose in the language of algebra. Now many algebraical problems involving three unknown or variable quantities admit of being generalised so as to give problems involving many such quantities. And as, on the one hand, to every algebraical problem involving unknown quantities or variables by ones, or by twos, or by threes, there corresponds a problem in geometry of one or of two or of three dimensions, so on the other it may be said that to every algebraical problem involving many variables there corresponds a problem in geometry of many dimensions.

There is, however, another aspect under which even ordinary space presents to us a four-fold, or indeed a manifold character. In modern physics space is not regarded as a vacuum in which bodies are placed and forces have play, but rather as a plenum with which matter is co-extensive. And from a physical point of view the properties of space are the properties of matter, or of the medium which fills it. Similarly from a mathematical point of view, space may be regarded as a *locus in quo*, as a plenum, filled with those elements of geometrical magnitude which we take as fundamental. These elements need not always be the same. For different purposes different elements may be chosen; and upon the degree of complexity of the subject of our choice will depend the internal structure or manifoldness of space.

Thus, beginning with the simplest case, a point may have any singly infinite multitude of positions in a line, which gives a one-fold system of points in a line. The line may revolve in a plane about any one of its points, giving a two-fold system of points in a plane; and the plane may revolve about any one of the lines, giving a three-fold system of points in space.

Suppose, however, that we take a straight line as our element, and conceive space as filled with such lines. This will be the case if we take two planes, *e.g.*, two parallel planes, and join every point in one with every point in the other. Now the points in a plane form a two-fold system, and it therefore follows that the system of lines is four-fold; in other words, space regarded as a plenum of lines is four-fold. The same result follows from the consideration that the lines in a plane, and the planes through a point, are each two-fold.

Again, if we take a sphere as our element we can through any point as a centre draw a singly infinite number of spheres, but the number of such centres is triply infinite; hence space as a plenum of spheres is four-fold. And generally, space as a plenum of surfaces has a manifoldness equal to the number of constants required to determine the surface. Although it would be beyond our present purpose to attempt to pursue the subject further, it should not pass unnoticed that the identity in the four-fold character of space, as derived on the one hand from a system of straight lines, and on the other from a system of spheres, is intimately connected with the principles established by Sophus Lie in his researches on the correlation of these figures.

If we take a circle as our element we can around any point in a plane as a centre draw a singly infinite system of circles; but the number of such centres in a plane is doubly infinite; hence the circles in a plane form a three-fold system, and as the planes in space form a three-fold system, it follows that space as a plenum of circles is six-fold.

Again, if we take a circle as our element, we may regard it as a section either of a sphere, or of a right cone (given except in position) by a plane perpendicular to the axis. In the former case the position of the centre is three-fold; the directions of the plane, like that of a pencil of lines perpendicular thereto, two-fold; and the radius of the sphere one-fold; six-fold in all. In the latter case, the position of the vertex is three-fold; the direction of the axis two-fold; and the distance of the plane of section one-fold; six-fold in all, as before. Hence space as a plenum of circles is six-fold.

Similarly, if we take a conic as our element we may regard it as a section of a right cone (given except in position) by a plane. If the nature of the conic be defined, the plane of section will be inclined at a fixed angle to the axis; otherwise it will be free to take any inclination whatever. This being so, the position of the vertex will be three-fold, the direction of the axis two-fold, the distance of the plane of section from the vertex one-fold, and the direction of that plane one-fold if the conic be defined, two-fold if it be not defined. Hence, space as a plenum of definite conics will be seven-fold, as a plenum of conics in general, eight-fold. And so on for curves of higher degrees.

This is, in fact, the whole story and mystery of manifold space. If not seriously regarded as a reality in the same sense as ordinary space, it is a mode of representation, or a method which, having served its purpose, vanishes from the scene. Like a rainbow, if we try to grasp it, it eludes our very touch; but, like a rainbow, it arises out of real conditions of known and tangible quantities, and if rightly apprehended it is a true and valuable expression of natural laws, and serves a definite purpose in the science of which it forms part.

Illustrations.

Again, if we seek a counterpart of this in common life, I might remind you that perspective in drawing is itself a method not altogether dissimilar to that of which I have been speaking; and that the third dimension of space, as represented in a picture, has its origin in the painter's mind, and is due to his skill, but has no real existence upon the canvas which is the groundwork of his art. Or again, turning to literature, when in legendary tales, or in works of fiction, things past and future are pictured as present, has not the poetic fancy brought time into correlation with the three dimensions of space, and brought all alike to a

common focus? Or once more, when space already filled with material substances is mentally peopled with immaterial beings, may not the imagination be regarded as having added a new element to the capacity of space, a fourth dimension of which there is no evidence in experimental fact?

Non-Euclid Geometry.

The third method proposed for special remark is that which has been termed non-Euclidean geometry, and the train of reasoning which has led to it may be described in general terms as follows: some of the properties of space which on account of their simplicity, theoretical as well as practical, have, in constructing the ordinary system of geometry, been considered as fundamental, are now seen to be particular cases of more general properties. Thus a plane surface and a straight line may be regarded as special instances of surfaces and lines whose curvature is everywhere uniform or constant. And it is, perhaps, not difficult to see that, when the special notions of flatness and straightness are abandoned, many properties of geometrical figures which we are in the habit of regarding as fundamental, will undergo profound modification. Thus a plane may be considered as a special case of the sphere, viz., the limit to which a sphere approaches when its radius is increased without limit. But even this consideration trenches upon an elementary proposition relating to one of the simplest of geometrical figures. In plane triangles the interior angles are together equal to two right angles; but in triangles traced on the surface of a sphere, this proposition does not hold good. To this, other instances might be added.

Further, these modifications may affect not only our ideas of particular geometrical figures, but the very axioms of the science itself. Thus, the idea which, in fact, lies at the foundation of Euclid's method that a geometrical figure may be moved in space without change of size or alteration of form, entirely falls away, or becomes only approximate in a space wherein dimension and form are dependent upon position. For instance, if we consider merely the case of figures traced on a flattened globe like the earth's surface, or upon an egg-shell, such figures cannot be made to slide upon the surface without change of form, as is the case with figures traced upon a plane or even upon a sphere. But, further still, these generalisations are not restricted to the case of figures traced upon a surface; they may apply also to solid figures in a space whose very configuration varies from point to point. We may, for instance, imagine a space in which our rule or scale of measurement varies as it extends, or as it moves about, in one direction or another; a space, in fact, whose geometric density is not uniformly distributed. Thus we might picture to ourselves such a space as a field having a more or less complicated distribution of temperature, and our scale as a rod instantaneously susceptible of expansion or contraction under the influence of heat; or we might suppose space to be even crystalline in its geometric formation, and our scale and measuring instruments to accept the structure of the locality in which they are applied. These ideas are doubtless difficult of apprehension, at all events at the outset; but Helmholtz has pointed out a very familiar phenomenon which may be regarded as a diagram of such a kind of space. The picture formed by reflection from a plane mirror may be taken as a correct representation of ordinary space, in which, subject to the usual laws of perspective, every object appears in the same form and of the same dimensions, whatever be its position. In like manner the picture formed by reflexion from a curved mirror may be regarded as the representation of a space wherein dimension and form are dependent upon position. Thus in an ordinary convex mirror objects appear smaller as they recede laterally from the centre of the picture; straight lines become curved; objects infinitely distant in front of the mirror appear at a distance only equal to the focal length behind. And by suitable modifications in the curvature of the mirror, representations could similarly be obtained of space of various configurations.

Its Meaning and Use.

The diversity in kind of these spaces is of course infinite; they vary with the mode in which we generalise our conceptions of ordinary space; but upon each as a basis it is possible to construct a consistent system of geometry, whose laws, as a matter of strict reasoning, have a validity and truth not inferior to those with which we are habitually familiar. Such systems having been actually constructed, the question has not unnaturally been asked, whether there is anything in nature or in the outer world to which they correspond; whether, admitting that for our limited experience ordinary geometry amply suffices, we may understand that for powers more extensive in range or more minute in definition some more general scheme would be requisite? Thus, for example, although the one may serve for the solar system, is it legitimate to suppose that it may fail to apply at distances reaching to the fixed stars, or to regions beyond? Or again, if our vision could discern the minute configuration of portions of space, which to our ordinary powers appear infinitesimally small, should we expect to find that all our usual geometry is but a special case, sufficient indeed for daily use, but after all only a rough approximation to a truer although perhaps more complicated scheme? Traces of these questions are in fact to be found in the writings of some of our greatest and most original mathematicians. Gauss, Riemann, and Helmholtz have thrown out suggestions radiating, as it were, in these various directions from a common centre; while Cayley, Sylvester, and Clifford in this country, Klein in Germany, Lobatscheffsky in Russia, Bolyai in Hungary, and Beltrami in Italy, with many others, have reflected similar ideas with all the modifications due to the chromatic dispersion or their individual minds. But to the main question the answer must be in the negative. And, to use the words of Newton, since "geometry has its foundation in mechanical practice," the same must be the answer until our experience is different from what it now is. And yet, all this notwithstanding, the generalised conceptions of space are not without their practical utility. The principle of representing space of one kind by that of another, and figures belonging to one by their analogues in the other, is not only recognised as legitimate in pure mathematics, but has long ago found its application in cartography. In maps or charts, geographical positions, the contour of coasts, and other features, belonging in reality to the earth's surface, are represented on the flat; and to each mode of representation, or projection as it is called, there corresponds a special correlation between the spheroid and the plane. To this might perhaps be added the method of descriptive geometry, and all similar processes in use by engineers, both military and civil.

It has often been asked whether modern research in the field of pure mathematics has not so completely outstripped its physical applications as to be practically useless; whether the analyst and the geometer might not now, and for a long time to come, fairly say, "hic artem remumque repono," and turn his attention to mechanics and to physics. That the Pure has outstripped the Applied is largely true; but that the former is on that account useless is far from true. Its utility often crops up at unexpected points: witness the aids to classification of physical quantities, furnished by the ideas (of Scalar and Vector) involved in the "Calculus of Quaternions;" or the advantages which have accrued to physical astronomy from Lagrange's "Equations," and from Hamilton's "Principle of Varying Action;" on the value of complex quantities, and the properties of general integrals, and of general theorems on integration for the theories of electricity and magnetism. The utility of such researches can in no case be discounted, or even imagined beforehand; who, for instance, would have supposed that the calculus of forms or the theory of substitutions would have thrown much light upon ordinary equations; or that Abolian functions and hyperelliptic transcendents would have told us anything about the properties of curves; or that the calculus of operations would have helped us in any way towards the figure of the earth? But upon such technical points I must not now dwell. If, however, as I hope, it has been sufficiently shown that any of these more extended ideas enable us to combine together, and to deal with as one, properties and processes which from the ordinary point of view present marked distinctions, then they will have justified their own existence; and in using them we shall not have been walking in a vain shadow, nor disquieting our brains in vain.

Mathematical Symmetry.

These extensions of mathematical ideas would, however, be overwhelming, if they were not compensated by some simplifications in the processes actually employed. Of these aids to calculation I will mention only two, viz., symmetry of form and mechanical appliances; or, say, mathematics as a fine art, and mathematics as a handicraft. And first, as to symmetry of form. There are many passages of algebra in which long processes of calculation at the outset seem unavoidable. Results are often obtained in the first instance through a tangled maze of

formulæ, where at best we can just make sure of their process step by step, without any general survey of the path which we have traversed, and still less of that which we have to pursue. But almost within our own generation a new method has been devised to clear this entanglement. More correctly speaking, the method is not new, for it is inherent in the processes of algebra itself, and instances of it, unnoticed perhaps or disregarded, are to be found cropping up throughout nearly all mathematical treatises. By Lagrange, and to some extent also by Gauss, among the older writers, the method of which I am speaking was recognised as a principle; but beside these perhaps no others can be named until a period within our own recollection. The method consists in symmetry of expression. In algebraical formulæ combinations of the quantities entering therein occur and recur; and by a suitable choice of these quantities the various combinations may be rendered symmetrical and reduced to a few well-known types. This having been done, and one such combination having been calculated, the remainder, together with many of their results, can often be written down at once, without further calculations, by simple permutations of the letters. Symmetrical expressions, moreover, save as much time and trouble in reading as in writing. Instead of wading laboriously through a series of expressions which, although successively dependent, bear no outward resemblance to one another, we may read off symmetrical formulæ, of almost any length, at a glance. A page of such formulæ becomes a picture: known forms are seen in definite groupings; their relative positions, or perspective as it may be called, their very light and shadow, convey their meaning almost as much through the artistic faculty as through any conscious ratiocinative process. Few principles have been more suggestive of extended ideas or of new views and relation than that of which I am now speaking. In order to pass from questions concerning plane figures to those which appertain to space, from conditions having few degrees of freedom to others which have many—in a word, from more restricted to less restricted problems—we have in many cases merely to add lines and columns to our array of letters or symbols already formed, and then read off pictorially the extended theorems.

Mechanical Methods.

Next as to mechanical appliances. Mr. Babbage, when speaking of the difficulty of insuring accuracy in the long numerical calculations of theoretical astronomy, remarked that the science which in itself is the most accurate and certain of all had, through these difficulties, become inaccurate and uncertain in some of its results. And it was doubtless some such consideration as this, coupled with his dislike of employing skilled labour where unskilled labour would suffice, which led him to the invention of his calculating machines. The idea of substituting mechanical for intellectual power has not lain dormant; for beside the arithmetical machines, whose name is legion (from Napier's Bones, Earl Stanhope's calculator, to Schultz's and Thomas's machines now in actual use), an invention has lately been designed for even a more difficult task.[1] Prof. James Thomson has in fact recently constructed a machine which, by means of the mere friction of a disc, a cylinder, and a ball, is capable of effecting a variety of the complicated calculations which occur in the highest application of mathematics to physical problems. By its aid it seems that an unskilled labourer may, in a given time, perform the work of ten skilled arithmeticians. The machine is applicable alike to the calculation of tidal, of magnetic, of meteorological, and perhaps also of all other periodic phenomena. It will solve differential equations of the second and perhaps of even higher orders. And through the same invention the problem of finding the free motions of any number of mutually attracting particles, unrestricted by any of the approximate suppositions required in the treatment of the lunar and planetary theories, is reduced to the simple process of turning a handle.

When Faraday had completed the experimental part of a physical problem, and desired that it should thenceforward be treated mathematically, he used irreverently to say, "Hand it over to the calculators." But truth is ever stranger than fiction; and if he had lived until our day, he might with perfect propriety have said, "Hand it over to the machine."

Mathematics and Observation.

Had time permitted, the foregoing topics would have led me to point out that the mathematician, although concerned only with abstractions, uses many of the same methods of research as are employed in other sciences, and in the arts, such as observation, experiment, induction, imagination. But this is the less necessary because the subject has been already handled very ably, although with greater brevity than might have been wished, by Prof. Sylvester in his address to Section A at our meeting at Exeter.

Origin of Mathematical Ideas.

In an exhaustive treatment of my subject there would still remain a question which in one sense lies at the bottom of all others, and which through almost all time has had an attraction for reflective minds, viz., what was the origin of mathematical ideas? Are they to be regarded as independent of, or dependent upon, experience? The question has been answered sometimes in one way and sometimes in another. But the absence of any satisfactory conclusion may after all be understood as implying that no answer is possible in the sense in which the question is put; or rather that there is no question at all in the matter, except as to the history of actual facts. And, even if we distinguish, as we certainly should, between the origin of ideas in the individual and their origin in a nation or mankind, we should still come to the same conclusion. If we take the case of the individual, all we can do is to give an account of our own experience; how we played with marbles and apples; how we learnt the multiplication table, fractions, and proportion; how we were afterwards amused to find that common things conformed to the rules of number; and later still how we came to see that the same laws applied to music and to mechanism, to astronomy, to chemistry, and to many other subjects. And then, on trying to analyse our own mental processes, we find that mathematical ideas have been imbibed in precisely the same way as all other ideas, viz., by learning, by experience, and by reflection. The apparent difference in the mode of first apprehending them and in their ultimate cogency arises from the difference of the ideas themselves, from the preponderance of quantitative over qualitative considerations in mathematics, from the notions of absolute equality and identity which they imply.

If we turn to the other question, How did the world at large acquire and improve its idea of number and of figures? How can we span the interval between the savage who counted only by the help of outward objects, to whom fifteen was "half the hands and both the feet," and Newton or Laplace? The answer is the history of mathematics and its successive developments, arithmetic, geometry, algebra, &c. The first and greatest step in all this was the transition from number in the concrete to number in the abstract. This was the beginning not only of mathematics but of all abstract thought. The reason and mode of it was the same as in the individual. There was the same general influx of evidence, the same unsought for experimental proof, the same recognition of general laws running through all manner of purposes and relations of life. No wonder then if, under such circumstances, mathematics, like some other subjects, and perhaps with better excuse, came after a time to be clothed with mysticism; nor that, even in modern times, they should have been placed upon an *à priori* basis as in the philosophy of Kant.

Their Survival and Transition.

Number was so soon found to be a principle common to many branches of knowledge that it was readily assumed to be the key to all. It gave distinctness of expression, if not clearness of thought, to ideas which were floating in the untutored mind, and even suggested to it new conceptions. In "the one" "the all," "the many in one" (terms of purely arithmetic origin), it gave the earliest utterance to men's first crude notions about God and the world. In "the equal," "the solid," "the straight," and "the crooked," which still survive as figures of speech among ourselves, it supplied a vocabulary for the moral notions of mankind, and quickened them by giving them the power of expression. In this lies the great and enduring interest in the fragments which remain to us of the Pythagorean philosophy.

The consecutive processes of mathematics led to the consecutive processes of logic, but it was not until long after mankind had attained to abstract ideas that they attained to any clear notion of their connection with one another. The leading ideas of mathematics became the leading ideas of logic. The "one" and the "many" passed into the "whole" and its "parts;" and thence into the "universal" and the "particular." The fallacies of logic, such as the well-known puzzle of Achilles and the tortoise, partake of the nature of both sciences. And perhaps the conception of the infinite and the infinitesimal, as

[1] Royal Society's *Proceedings*, February 3, 1876, and May 9, 1878.

well as of negation, may have been in early times transferred from logic to mathematics. But the connection of our ideas of number is probably anterior to the connection of any of our other ideas. And as a matter of fact, geometry and arithmetic had already made considerable progress when Aristotle invented the syllogism.

General Ideas.

General ideas there were beside those of mathematics—true flashes of genius which saw that there must be general laws to which the universe conforms, but which saw them only by occasional glimpses, and through the distortion of imperfect knowledge; and although the only records of them now remaining are the inadequate representations of later writers, yet we must still remember that to the existence of such ideas is due not only the conception but even the possibility of physical science. But these general ideas were too wide in their grasp, and in early days at least were connected to their subjects of application by links too shadowy to be thoroughly apprehended by most minds, and so it came to pass that one form of such an idea was taken as its only form, one application of it as the idea itself; and philosophy, unable to maintain itself at the level of ideas, fell back upon the abstractions of sense, and, by preference, upon those which were most ready to hand, namely, those of mathematics. Plato's ideas relapsed into a doctrine of numbers; mathematics into mysticism, into Neo-Platonism, and the like. And so, through many long ages, through good report and evil report, mathematics have always held an unsought-for sway. It has happened to this science, as to many other subjects, that its warmest adherents have not always been its best friends. Mathematics have often been brought in to matters where their presence has been of doubtful utility. If they have given precision to literary style, that precision has sometimes been carried to excess, as in Spinoza and perhaps Descartes; if they have tended to clearness of expression in philosophy, that very clearness has sometimes given an appearance of finality not always true;[1] if they have contributed to definition in theology, that definitiveness has often been fictitious, and has been attained at the cost of spiritual meaning.[2] And, coming to recent times, although we may admire the ingenuity displayed in the logical machines of Earl Stanhope and of Stanley Jevons, in the formal logic of De Morgan, and in the calculus of Boole; although as mathematicians we may feel satisfaction that these feats (the possibility of which was clear *à priori*) have been actually accomplished; yet we must bear in mind that their application is really confined to cases where the subject matter is perfectly uniform in character, and that beyond this range they are liable to encumber rather than to assist thought.

Not unconnected with this intimate association of ideas and their expression is the fact that, which ever may have been cause, which ever effect, or whether both may not in turn have acted as cause and effect, the culminating age of classic art was contemporaneous with the first great development of mathematical science.[3] In an earlier part of this discourse I have alluded to the importance of mathematical precision recognised in the *technique* of art during the Cinquecento; and I have now time only to add that, on looking still further back, it would seem that sculpture and painting, architecture and music, nay even poetry itself, received a new, if not their first true, impulse at the period when geometric form appeared fresh chiselled by the hand of the mathematician, and when the first ideas of harmony and proportion rang joyously together in the morning tide of art.

Relations of Science to Literature and Art.

Whether the views on which I have here insisted be in any way novel, or whether they be merely such as from habit or from inclination are usually kept out of sight, matters little. But whichever be the case, they may still furnish a solvent of that rigid aversion which both literature and art are too often inclined to maintain towards science of all kinds. It is a very old story that, to know one another better, to dwell upon similarities rather than upon diversities, are the first stages towards a better understanding between two parties; but in few cases has it a truer application than in that here discussed. To recognise the common growth of scientific and other instincts until the time of harvest is not only conducive to a rich crop, but it is also a matter of prudence, lest, in trying to root up weeds from among the wheat, we should at the same time root up that which is as valuable as wheat. When Pascal's father had shut the door of his son's study to mathematics, and closeted him with Latin and Greek, he found on his return that the walls were teeming with formulæ and figures, the more congenial product of the boy's mind. Fortunately for the boy, and fortunately also for science, the mathematics were not torn up, but were suffered to grow together with other subjects. And all said and done, the lad was not the worse scholar or man of letters in the end. But, truth to tell, considering the severance which still subsists in education and during our early years between literature and science, we can hardly wonder if, when thrown together in the afterwork of life, they should meet as strangers; or if the severe garb, the curious implements, and the strange wares of the latter, should seem little attractive when contrasted with the light companionship of the former. The day is yet young, and in the early dawn many things look weird and fantastic which in fuller light prove to be familiar and useful. The outcomings of science, which at one time have been deemed to be but stumbling-blocks scattered in the way, may ultimately prove stepping-stones which have been carefully laid to form a pathway over difficult places for the children of "sweetness and of light."

Concluding Remarks.

The instances on which we have dwelt are only a few out of many in which mathematics may be found ruling and governing a variety of subjects. It is as the supreme result of all experience, the framework in which all the varied manifestations of nature have been set, that our science has laid claim to be the arbiter of all knowledge. She does not indeed contribute elements of fact, which must be sought elsewhere; but she sifts and regulates them; she proclaims the laws to which they must conform if those elements are to issue in precise results. From the data of a problem she can infallibly extract all possible consequences, whether they be those first sought, or others not anticipated; but she can introduce nothing which was not latent in the original statement. Mathematics cannot tell us whether there be or be not limits to time or space; but to her they are both of indefinite extent, and this in a sense which neither affirms nor denies that they are either infinite or finite. Mathematics cannot tell us whether matter be continuous or discrete in its structure; but to her it is indifferent whether it be one or the other, and her conclusions are independent of either particular hypothesis. Mathematics can tell us nothing of the origin of matter, of its creation or its annihilation; she deals only with it in a state of existence; but within that state its modes of existence may vary from our most elementary conception to our most complex experience. Mathematics can tell us nothing beyond the problems which she specifically undertakes; she will carry them to their limit, but there she stops, and upon the great region beyond which she is imperturbably silent.

Conterminous with space and coeval with time is the kingdom of mathematics; within this range her dominion is supreme; otherwise than according to her order nothing can exist; in contradiction to her laws nothing takes place. On her mysterious scroll is to be found written for those who can read it that which has been, that which is, and that which is to come. Everything material which is the subject of knowledge has number, order, or position; and these are her first outlines for a sketch of the universe. If our more feeble hands cannot follow out the details, still her part has been drawn with an unerring pen, and her work cannot be gainsaid. So wide is the

[1] For example, in Herbart's "Psychologie."

[2] A specimen will be found in the Moralia of Gregory the Great, Lib. I., c. xiv., of which I quote only the arithmetical part:—

"Quid in septenario numero, nisi summa perfectionis accipitur? Ut enim humanæ rationis causas de septenario numero taceamus, quæ afferunt, quòd idcirco perfectus sit, quia exprimo pari constat, et primo impari; ex primo, qui dividi potest, et primo, qui dividi non potest; certissimè scimus, quòd septenarium numerum Scriptura Sacra pro perfectione ponere consuevit. . . . . A septenario quippe numero in duodenarium surgitur. Nam septenarius suis in se partibus multiplicatus, ad duodenarium tenditur. Sive enim quatuor per tria, sive per quatuor tria ducantur, septem in duodecim vertuntur. . . . . Jam superiùs dictum est, quòd in quinquagenario numero, qui septem hebdomadibus ac monade additâ impletur, requies designatur; denario autem numero summa perfectionis exprimitur."

range of mathematical science, so indefinitely may it extend beyond our actual powers of manipulation, that at some moments we are inclined to fall down with even more than reverence before her majestic presence. But so strictly limited are her promises and powers, about so much that we might wish to know does she offer no information whatever, that at other moments we are fain to call her results but a vain thing, and to reject them as a stone when we had asked for bread. If one aspect of the subject encourages our hopes, so does the other tend to chasten our desires; and he is perhaps the wisest, and in the long run the happiest among his fellows, who has learnt not only mathematics, but also the larger lesson which they indirectly teach, namely, to temper our aspirations to that which is possible, to moderate our desires to that which is attainable, to restrict our hopes to that of which accomplishment, if not immediately practicable, is at least distinctly within the range of conception. That which is at present beyond our ken may, at some period and in some manner as yet unknown to us, fall within our grasp; but our science teaches us, while ever yearning with Goethe for "Light, more light," to concentrate our attention upon that of which our powers are capable, and contentedly to leave for future experience the solution of problems to which we can at present say neither yea nor nay.

It is within the region thus indicated that knowledge in the true sense of the word is to be sought. Other modes of influence there are in society and in individual life, other forms of energy beside that of intellect. There is the potential energy of sympathy, the actual energy of work; there are the vicissitudes of life, the diversity of circumstance, health, and disease, and all the perplexing issues, whether for good or for evil, of impulse and of passion. But although the book of life cannot at present be read by the light of science alone, nor the wayfarers be satisfied by the few loaves of knowledge now in our hands, yet it would be difficult to overstate the almost miraculous increase which may be produced by a liberal distribution of what we already have, and by a restriction of our cravings within the limits of possibility.

In proportion as method is better than impulse, deliberate purpose than erratic action, the clear glow of sunshine than irregular reflection, and definite utterances than an uncertain sound; in proportion as knowledge is better than surmise, proof than opinion; in that proportion will the mathematician value a discrimination between the certain and the uncertain, and a just estimate of the issues which depend upon one motive power or the other. While on the one hand he accords to his neighbours full liberty to regard the unknown in whatever way they are led by the noblest powers that they possess, so on the other he claims an equal right to draw a clear line of demarcation between that which is a matter of knowledge, and that which is at all events something else, and to treat the one category as fairly claiming our assent, the other as open to further evidence. And yet, when he sees around him those whose aspirations are so fair, whose impulses so strong, whose receptive faculties so sensitive, as to give objective reality to what is often but a reflex from themselves, or a projected image of their own experience, he will be willing to admit that there are influences which he cannot as yet either fathom or measure, but whose operation he must recognise among the facts of our existence.

SECTION C.

GEOLOGY.

OPENING ADDRESS BY THE PRESIDENT, JOHN EVANS, D.C.L., F.R.S., F.G.S., &c.

IN opening the proceedings of this Section, I cannot but call attention to the fact that the present is the third occasion on which the British Association has met in this city, its first meeting here having taken place in the year 1835, or forty-three years ago. On that occasion, as indeed for many years afterwards, the two distinct, though to some extent cognate branches of study, geology and geography, were classed in the same section, and its president was a man of whom Irish science may well be proud, and who, I am thankful to say, is still living to enjoy his well-deserved honours—the veteran geologist, Sir Richard John Griffith, the author of the first geological map of Ireland. It seems hardly credible that the construction of this map was commenced in the summer of 1812, or sixty-six years ago; but the records of the Geological Society of London testify to the still more remarkable fact that Sir Richard Griffith was elected a fellow of that Society in 1808—seventy years ago. Indeed, in 1854, when the Wollaston medal was awarded to the then Dr. Griffith, the president, the late Prof. Edward Forbes, spoke as he said reverentially to one of the earliest members of the Society, and to a geologist who appeared in print before he, the president, was born. It was well said on that occasion that the map lately mentioned was one of the most remarkable geological maps ever produced by a single geologist; and I make no doubt that those who are at present engaged on the Geological Survey of this island will testify, as did their predecessors, to the value of this "surprising monument of observation and skill." When speaking of the Geological Survey of Ireland, it will not, I am sure, be thought out of place if I offer here a tribute of respect to the memory of one who was originally a student in the college within whose walls we are assembled, and who subsequently occupied posts of the highest importance in connection with the Geological Society of Dublin and the Geological Survey of Ireland, besides filling the professorial Chair of Geology in this University: I mean Dr. Thomas Oldham, the late Director of the Geological Survey of India. With the marvellous amount of work which he was enabled to accomplish in that country you are all acquainted, and you will all share in the regret that the period of his well-earned retirement—that "requies optimorum meritorum"—should have been so quickly cut short by death. His name will, however, long survive, and future students of geology will have no difficulty in recognising the distinguished labourer in their science after whom the Cambrian *Oldhamia* of the Wicklow hills so worthily received its name.

But to return to this Association.

On the next occasion of its meeting in Dublin, in 1857, Section C had become devoted to geology alone, and geography was excluded, the president being Lord Talbot de Malahide, a nobleman whom also we still have among us, and who is alike well known to archæologists and geologists.

As the last meeting of the Association in this city took place twenty-one years ago, it would at first sight appear that in opening our proceedings I might with propriety dwell on the progress which has been made within that period in the development of the geology of Ireland. I must, however, remind you that it is only four years since the Association held its meeting in what I may almost call the neighbouring town of Belfast, when the accomplished chief of the Geological Survey in Ireland presided over this section and delivered an address, in which some of the more interesting features of the country, especially those of the volcanic district of the north-east of this island, were discussed. During the present year, moreover, he has published his comprehensive work on the "Physical Geology and Geography of Ireland," which I commend to you as far more likely to call your attention to the characteristic features of the country and the latest discoveries with regard to its geology than anything I could compile.

In addition to this, there has appeared during the present year another interesting volume, which records the impressions of a highly intelligent foreign geologist on visiting this country. I mean the "Aus Irland" of Dr. Arnold von Lassaulx, Professor of Mineralogy in the University of Breslau. For this volume, in which shrewd remarks on the country and its inhabitants are mingled with geological observations and valuable comparisons of the Irish formations with those of other countries, we are indebted to the meeting of the British Association having been held two years ago at Glasgow, which attracted the author to visit the British Islands.

So much having lately been published upon the geology of this country, I shall content myself with making a very few general observations with regard to it, and propose subsequently to touch briefly on some of those questions which, within the last twelve months, have occupied the attention of those who are engaged in the advancement of our science.

As to the geology of this country, I may observe that we are here assembled just on the edge of that great central plain which forms so important a feature in the map of Ireland, and which stretches from Dublin Bay on the east coast, to Galway Bay on the west, with hardly a portion of it attaining to an elevation of 300 feet above the sea, over a tract of country nearly 150 miles in extent in almost every direction.

The boundaries of this great plain and those of the carboniferous limestone almost coincide, so that we have here the somewhat remarkable feature of a formation which in England is of such a character as to have received the name of the mountain limestone, constituting in the neighbouring island nearly the whole of the plain country. In some of the north-western

counties, however, as for instance Fermanagh and Sligo, it assumes its more mountainous character. Nearly the whole of this central plain is overlain with boulder clay, limestone gravel, or middle drift, and extensive bogs, so that the subjacent rock is but occasionally seen. In several places detached bosses of old red sandstone rise through the limestone, and there is also good reason for believing, with Prof. Hull, that the whole of the area was at one time covered with the upper members of the carboniferous group, including the true coal measures, of which unfortunately but small patches remain, and those upon the margin of the plain. From the absence of the upper palæozoic, mesozoic, and cainozoic formations over the area, Prof. Hull has arrived at the conclusion that the surface remained in the condition of dry land, while that of England was being submerged beneath the waters of the sea, over the bed of which nearly all these formations were deposited. To a certain extent, however, he leaves it an open question whether some of the mesozoic strata which occur over the north-east of Ireland may not have been deposited over the centre and south. The amount of denudation over this central area has, no doubt, been such that the chances of even Prof. Judd finding traces of these later deposits appear at first sight to be but small; but whether the whole of this vast amount of denudation is due to the wasting influence of rain, rivers, and other sub-aërial agents of erosion, is a question which I venture to regard as at all events open to discussion. It appears to be the case that in some parts of the north of Ireland the whole of the upper carboniferous beds had been denuded before the deposition of any permian strata, as these are deposited immediately on the carboniferous limestone; and if this amount of denudation had taken place in pre-permian times in the north, there seems a possibility of the same having been the case in central Ireland. If so, it is possible that some traces of the later deposits may yet be found on the central plain. Certainly, if we are still to regard the white chalk as a deep-sea deposit, the cretaceous rocks of the north-east of Ireland must have at one time extended farther south than they do at present, and somewhere or other there must have been shore deposits of that period formed farther south than the Upper Greensand of Antrim. The careful investigations of Prof. Judd have largely extended our knowledge of the secondary rocks of the western coast and islands of Scotland, and he has been able to show that the Jurassic series of the Western Highlands could not have had a thickness of less than three thousand feet. It is therefore hard to believe that with such a development in so closely neighbouring a district, the deposits of the same age in Ireland can have been restricted to their present area.

Prof. Judd considers that the amount of denudation in the Scottish Highlands since the mesozoic, and even the miocene period, has been enormous, and that the great surface features of the Highlands were produced in pliocene times. It seems therefore possible, if not probable, that so long a period of exposure to sub-aërial influence as that assigned to the central plain of Ireland by Prof. Hull would have resulted in a more uneven land surface than that which we now find. At all events, the history of this remarkable physical feature is one which is of high interest, and can hardly as yet be considered as closed.

With regard to the mountainous districts surrounding the central plain, we shall, I believe, have the opportunity of visiting some parts of the Wicklow Mountains, a district from which a portion, at all events, of the native gold of Ireland was procured in ancient times, as indeed it continues to be. Of the abundance of gold in this country in early times, a glance at the magnificent collection of ancient ornaments preserved in the museum of the Royal Irish Academy will serve to give an idea. Even in times more recent than those in which the bulk of these ornaments were made, gold was an important product of this country, and I am tempted to quote a few lines from an early English poem, "The Libell of Englishe Policye," written in the year 1436. In treating of the commodities of Ireland, the author says that the country is

"So large, so gode, and so commodious,
That to declare is straunge and merveilous.
For of silver and gold there is the ore
Among the wilde Irish, though they be pore;
For they ar rude and can thereon no skille,
So that, if we hadde ther pese and good wille,
To mine and fine and metal for to pure
In wilde Irishe mighte we find the cure;
As in Londone saith a jewellere
Which broughte from thennes gold oor to us here,
Wherof was fined metal gode and clene,
That at the touch no better coud be sene."

Sir William Wilde has observed that the south-western half of Ireland has yielded a greater amount of gold antiquities than the north-western, and probably this would hold good with regard to the production of the metal itself, though it has been found in the counties of Antrim, Tyrone, and Derry, as well as in those of Dublin, Wicklow, Wexford, and Kildare.

The north-east of Ireland possesses, however, another geological feature peculiar to itself in that great expanse of volcanic beds which formed the subject of Professor Hull's address to this section at the Belfast meeting. My only object in now mentioning them is again to call attention to their containing the only remains of a miocene flora which are to be found in this island. Analogous beds were detected in the corresponding basalts in the Island of Mull by the Duke of Argyll in 1851. With the exception of the Hempstead beds of the Isle of Wight, which should probably be classed as oligocene, and the Bovey Tracey beds of Devonshire, these are almost the only deposits of miocene age in the British Isles. The contrast presented by the scarcity of deposits of this period in Britain with their abundance in the north-west, centre, and south of France, Switzerland, and generally in the south of Europe, is striking. Instead of thick deposits covering hundreds of square miles of country, like the miocene beds bordering the Pyrenees or those of the great system of the Auvergne, we have small patches owing their preservation either to volcanic outbursts having covered them up, or to some favourable circumstance having preserved them from total denudation. Whether we are to assume with the late Prof. Edward Forbes, that the general dearth of these strata in the British Isles arose from the extent of dry land which prevailed during the long interval between the eocene and pliocene periods, or whether we assume the former existence of widespread marine deposits which have since been entirely removed, the case is not one without difficulty. At all events, the absence of representatives of this period within the British area has a tendency to prevent a due appreciation of the enormous extent of the miocene period being generally felt in this country. Nor, generally speaking, do we, I think, take a fair estimate of the remoteness in time to which we must date back the commencement of that lengthened period. Prof. Haughton, judging from the maximum observed thickness of each successive deposit, has calculated that a greater interval of time now separates us from the miocene period than that which was occupied in producing all the secondary and tertiary strata from the triassic to the miocene epoch, and, without endorsing the whole of my accomplished friend's conclusions, I incline to concur in such an estimate. When it is considered that the Ballypalidy beds of Antrim and the Lough Neagh clays are the sole representatives in Ireland of two periods of such length and importance as the miocene and pliocene, their high interest will be more apparent, and I trust that no opportunity of minutely studying them will be neglected.

There is one other point with regard to Irish geology on which it will be well to say a few words, though it is of a negative rather than a positive character. I mean the absence, so far as at present known, of palæolithic implements in this country. It is true that Prof. Hull, in the book to which I am so much indebted, speaks of a raised beach on the Antrim coast as containing worked flints of that rude form and finish known as palæolithic; but this is a slip of the pen, by which the author has fallen into the not uncommon error of applying a term which is merely significant of the age of the implements to their external character. However rude may be the workmanship of the flint implements found at Kilroot, they belong to the neolithic, and not to the palæolithic period. So far as I am aware no example of any implement belonging to the age of the mammoth, rhinoceros, and other members of the quaternary fauna has as yet been found in Ireland. Indeed, the remains of *Elephas primigenius* and its associates are of exceedingly rare occurrence in this country, though they have been found with those of bear and reindeer in the Shandon Cave near Dungarvan. It is, of course, impossible to foretell what future researches may bring to light; but judging from analogy it seems hardly probable that until ancient river-gravels containing the remains of the quaternary group of mammals are found in this island, veritable palæolithic instruments will be discovered. The association of the two classes of remains is so constant that we may fairly assume that the animals formed the principal food of the palæolithic hunters, and that any causes which lead to the absence of the one class will lead to the absence of the other also.

There, is, however, one member of that old quaternary group

which is far more abundant in Ireland than it is in England or on the continent of Europe—the *Megaceros*—which has rightly received the appellation of *Hibernicus*.

I hope that we may have an opportunity, under the guidance of Mr. Richard Moss, of seeing some of the remains of this "antlered monarch of the waste" in the position in which they were originally interred, and it will be an interesting question for consideration whether these remains can be regarded as of the same geological age as those of the English caves and river-gravels, or whether they do not for the most part belong to what Prof. Boyd Dawkins has termed the pre-historic period. It seems by no means improbable that this gigantic stag survived in this country for ages after he had become extinct in other lands, and that the view held by Prof. Hull of his extinction being due to persecution by man is correct. If this be so it would seem to follow that the human occupation of Ireland is of far more recent date than that of the sister country.

And this brings me to one of those questions which have of late been occupying the attention of geologists. I mean the date which is to be assigned to the implement-bearing beds of palæolithic age in England. Dr. James Geikie has held that for the most part they belong to an interglacial episode towards the close of the glacial period, and regards it as certain that no palæolithic bed can be shown to belong to a more recent date than the mild era that preceded the last great submergence.

His follower, Mr. Skertchley, records the finding of palæolithic implements in no less than three interglacial beds, each underlying boulder clays of different ages and somewhat different characters, the Hessle, the purple, and the chalky boulder clay. This raises two main questions, first, as to how far Dr. Croll's theory of the great alternations of climate during the glacial period can be safely maintained; and secondly, how far the observations as to the discovery of implements in the so-called Brandon beds underlying the chalky boulder clay can be substantiated. Another question is how far the palæolithic deposits can be divided into those of modern and ancient valleys, separated from each other by the purple boulder clay, and the later of the two older than the Hessle beds. It would be out of place here to discuss these questions at length. I will only observe, that in a considerable number of cases the gravels containing the implements can be distinctly shown to be of much later date than the chalky boulder clay, and that if the implements occur in successive beds in the same district, each separated from the other by an enormous lapse of time, during which the whole country was buried beneath incredibly large masses of invading ice, and the whole mammalian fauna was driven away, it is a very remarkable circumstance. It is not the less remarkable because this succession of different palæolithic ages seems to be observable in one small district only, and there is as close a resemblance between the instruments of the presumably different ages as there is between those of admittedly the same date. I have always maintained the probability of evidence being found of the existence of Man at an earlier period than that of the post-glacial or quaternary river gravels, but, as in all other cases, it appears to me desirable that the evidence brought forward should be thoroughly sifted and all probability of misapprehension removed before it is finally accepted. In the present state of our knowledge, I do not feel confident that the evidence as to these three successive palæolithic deposits has arrived at this satisfactory stage. At the same time is must be borne in mind that if we make the palæolithic period to embrace not only the river gravels but the cave deposits of which the south of France furnishes such typical examples, its duration must have been of vast extent.

In connection with the question of glacial and interglacial periods, I may mention that of climatal changes in general, which has formed another subject to which much attention has of late been given. The return of the Arctic Expedition, and the reports of the geological observations made during its progress, which have been published by Captain Feilden, one of the naturalists to the expedition, in conjunction with Mr. De Rance and Prof. Heer, have conferred additional interest on the question of possible changes in the position of the poles of the earth, and on other kindred speculations. Near Discovery Harbour, about latitude 81° 40', miocene beds were found containing a flora somewhat differing from that which was already known to exist within the Arctic regions. "The Grinnell Land lignite," say the authors of the report, "indicates a thick peat moss, with probably a small lake, with water-lilies on the surface of the water, and reeds on the edges, with birches, poplars, and taxodiums on the banks, and with pines, firs, spruce, elms, and hazel-bushes on the neighbouring hills." When we consider that all of the genera here represented have their present limits at least from twelve to fifteen degrees further south, while the taxodium is now confined to Mexico and the south of the United States, such a sylvan landscape as that described seems entirely out of place in a district within six hundred miles of the pole, to which indeed, if land then extended so far, these Arctic forests must have also extended in miocene times. Making all allowance for the possibility of the habits of such plants being so changed that they could subsist without sunlight during six months of a winter of even longer duration, I cannot see how so high a temperature as that which appears necessary, especially for the evergreen varieties, could have been maintained, assuming that Grinnell Land was then as close to the North Pole as it is at the present day. Nor is this difficulty decreased when we look back to formations earlier than the miocene, for the flora of the secondary and palæozoic rocks of the Arctic regions is identical in character with that of the same rocks when occurring twenty or thirty degrees farther south, while the corals, encrinites, and cephalopods of the carboniferous limestone are such as, from all analogy, might be supposed to indicate a warm climate.

The general opinion of physicists as to the possibility of a change in the position of the earth's axis has recently undergone modifications somewhat analogous in character to those which, in the opinion of some geologists, the position of the axis has itself undergone. Instead of a fixed dogma as to the impossibility of change, we find a divergence of mathematical opinion and variations of the pole differing in extent, allowed by different mathematicians who have of late gone into the question, as, for instance, the Rev. J. F. Twisden,[1] Mr. George Darwin,[2] Prof. Haughton,[3] the Rev. E. Hill,[4] and Sir William Thomson.[5] All agree in the theoretical possibility of a change in the geographical position of the earth's axis of rotation being effected by a redistribution of matter on the surface, but they do not appear to be all in accord as to the extent of such changes. Mr. Twisden, for instance, arrives at the conclusion that the elevation of a belt twenty degrees in width, such as that which I suggested in my presidential address to the Geological Society in 1876, would displace the axis by about ten miles only, while Prof. Haughton maintains that the elevation of two such continents as Europe and Asia would displace it by about sixty-nine miles, and Sir W. Thomson has not only admitted, but asserted as highly probable, that the poles may have been in ancient times "very far from their present geographical position, and may have gradually shifted through ten, twenty, thirty, forty, or more degrees without at any time any perceptible sudden disturbance of either land or water."

I am glad to think that this question, to which I to some extent assisted to direct attention, has been so fully discussed, but I can hardly regard its discussion as being now finally closed. It appears to me doubtful whether eventually it will be found possible to concede to this globe that amount of solidity and rigidity which at present it is held to possess, and which, to my mind at all events, seems to be in entire disaccordance with many geological phenomena. Yet this, as the Rev. O. Fisher[6] has remarked, is presupposed in all the numerical calculations which have been made. I am also doubtful whether in the calculations which have been made, sufficient regard has been shown to the fact that a great part of the exterior of our spheroidal globe consists of fluid which, though of course connected with the more solid part of the globe by gravity, is readily capable of readjusting itself upon its surface, and may, to a great extent, be left out of the account in considering what changes might arise from the disturbance of the equilibrium of the irregular spherical or spheroidal body which it partially covers. It appears to me also possible that some disturbances of equilibrium may take place in a mysterious manner by the redistribution of matter or otherwise in the interior of the globe. Capt. F. J. Evans,[7] arguing from the changes now going on in terrestrial magnetism, has suggested the possibility of some secular changes being due to internal, and not to external causes; and it really be true that there is a difference between the longest and shortest equatorial radii of

7 NATURE, vol. xviii. p. 80.

the earth, amounting to six thousand three hundred and seventy-eight feet,[1] such a fact would appear to point to a great want of homogeneity in the interior of our planet, and might suggest a possible cause for some disturbance of equilibrium.

I have mentioned Prof. Haughton among those who, from mathematical considerations, have arrived at the conclusion that a geographical change in the position of the axis of rotation of the earth is not only possible but probable. In a recent paper, however, he has maintained that notwithstanding this possibility or probability, we can demonstrate that the pole has not sensibly changed its position during geological periods. He arrives at this conclusion by pointing out that in the Parry Islands, Alaska and Spitzbergen, there are triassic and Jurassic deposits of much the same tropical character, and then by a geometrical method fixing the north pole somewhere near Pekin, and the south pole in Patagonia, within seven hundred miles of a spot where Jurassic ammonites occur, shows that such a theory is untenable. In the same way he fixes the pole in miocene times near Yakutsk, within eight hundred miles of certain miocene coal-beds of the Japanese islands. These objections are at first sight startling, but I think it will be found that if, instead of drawing great circles through certain points, we regard those points as merely isolated localities in a belt of considerable width, there is no need of fixing the pole of either the Jurassic or the miocene period with that amount of nicety with which Prof. Haughton has ascertained its position. The belt may indeed be made to contain the very places on which the objection is founded. Still the method proposed is a good one, and I hope that as our knowledge of foreign geology extends it may be still further pursued. There is, however, one farther consideration to be urged, and that is as to the safety of regarding all deposits of one geological period as contemporaneous in time. Although an almost identical flora may be discovered in two widely-separated beds, it appears to me that chronologically they are more probably of different ages than absolutely contemporaneous; and, inasmuch as the duration of the miocene period must have been enormous, there would be time—if once we assume the wandering of the poles—for such wandering to have been considerable between the beginning and end of the period.

I must not, however, detain you longer upon this phase of geological speculation, but will advert to a subject of more practical interest, the discovery of palæozoic rocks under London. So long ago as 1856 the Kentish Town boring had shown that immediately below the gault red and variegated sandstones and clays occurred, which Professor Prestwich regarded as probably of old red or Devonian age. The boring of Messrs. Meux & Co. has now shown that under Tottenham Court Road, at a depth of little more than nine hundred feet from the surface, there are true Devonian beds, with characteristic fossils, and that Mr. Godwin Austen's prophecy of the existence of palæozoic rocks at an accessible depth under London has proved true. Prof. Prestwich, from a consideration of the French and Belgian coal-fields, inclines to the belief that in the district north of London carboniferous strata may be found. Unfortunately the expense of conducting deep borings, even with the admirable appliances of the Diamond Boring Company, is so great that I almost despair of another experimental borehole, like that carried out in the Wealden district under the auspices of Mr. Willett, being undertaken.

In the department of theoretical geology I would call your attention to some experiments by M. Daubrée, of which he has given accounts at different times to the French Academy of Sciences. In these experiments he has attempted to reproduce on a small scale various geological phenomena, such as faulting, cleavage, jointing, and the elevation of mountain chains. Although the analogy between work in the laboratory and that on the grand scale of nature may not in all cases be perfect, yet these experiments are in the highest degree instructive, and reflect no little credit on the ingenuity of the distinguished chief of the École des Mines.

With regard to recent progress in palæontology, I must venture to refer you to Prof. Alleyne Nicholson's inaugural address lately delivered to the Edinburgh Geological Society, but I cannot pass over in silence the magnificent discoveries in North America, which are principally due to the researches of Profs. Marsh, Leidy, and Cope. The *Diceratherium*, a rhinoceros with two horns placed transversely, and the *Dinoceras*, somewhat allied to the elephant, but with six horns, arranged in pairs, are as marvellous as some of the beasts seen by Sir John Maundeville on his travels, or heard of by Pliny. But perhaps the most remarkable series of remains ever discovered are those which so completely link the existing horse with the *Eohippus* and *Orohippus*, and still farther extend the pedigree of the genus *Equus*, which had already been some years ago so ably traced by Prof. Huxley.

[1] Thomson and Tait, "Phil." p. 648.

Of these American discoveries, as well as those made in the tertiary beds of Europe, M. Albert Gaudry has largely availed himself in his recent beautiful volume on the links in the animal world in geological times, a work which will long be a text-book on the inter-relation of different orders, genera, and species. I am tempted to make use of some portions of M. Gaudry's own analysis of the book, which he communicated to the Geological Society of France. Beginning with the marsupials of the close of the secondary and beginning of the tertiary period, he shows that they are succeeded by such animals as the *Pterodon*, the *Hyænodon*, the *Proviverra*, and *Arctocyon*, which present a mixture of marsupial and placental characters, and to some extent justify a theory of the transition from one order to the other. He next examines the marine mammalia, and points out that, so far as at present known, they make their appearance later than those of the land, and that the examination of the pelvis of the *Halitherium* tends to support the idea that the mammals, such as the sirenians, which at the present day have no hind limbs, are descended from terrestrial quadrupeds, for those limbs in the *Halitherium* are much less reduced than in its recent successors, the dugong and manatee. After tracing the numerous links which are to be found between the extinct and living pachydermata, he proceeds to show that, notwithstanding the great distance between them and the ruminants, transitions may be seen. The earliest ruminants were devoid of horns and antlers, but possessed upper incisors, and by a comparison of the molars of different genera it may readily be conceived how the large bosses of the omnivorous teeth of the pachyderms gradually shaded into the small crescents of the teeth of the ruminants. At the same time the passage from the heavy and complicated extremities of the limbs of the pachyderms to the simpler and lighter feet of the ruminants can be traced. The history of the horse family is also discussed, and the descent of existing proboscidians from the mastodonts is shown to be probable, though the previous forms from which the mastodonts and dinotheria are derived are as yet unknown. Nor can the origin of the carnivora as yet be suggested, though passages between the six existing families of the order may be observed. In conclusion M. Gaudry devotes a chapter to the quadrumana, and thinks that palæontological observations tend to diminish the isolation in which these mammals now stand with regard to the other orders.

One of the most important features insisted on by M. Gaudry is that to which I have already alluded—the development of the complicated molars of most mammals. His view is that by a comparison with early and with fœtal forms the probability may be shown of these compound teeth being made up of what in earlier forms were simple teeth—or, as he has termed them, denticules—which have coalesced in the same manner as have some other parts of the normal bony skeleton. In the compound teeth the denticules in some cases preserve their original conical form, as in the pig tribe; in others are elongated transversely, so as by their junction to form ridges, as in the tapirs; while in others, again, they are drawn out into longitudinal crescents, as in the ruminants. Between these forms there are, of course, innumerable transitions. They do not, however, appear to me to affect the importance of M. Gaudry's observations, which must be regarded as of the highest value in all attempts to trace the inter-relation of different forms of mammalian life. I must not, however, detain you longer on this subject, as I trust that I have said enough to show the importance and interest of this book.

The discoveries of early forms of birds with teeth do not come within M. Gaudry's province; but Prof. Marsh has largely added to our knowledge of these remarkable forms. The tertiary *Odontopteryx toliapicus* from Sheppey, described by Prof. Owen, seems rather to be endowed with bony tooth-like processes in the jaw than actual teeth, and the head of the *Argillornis* from the same locality is at present unknown. But the *Hesperornis* and *Ichthyornis* from the cretaceous beds of America possess veritable teeth, in the one case set in a long groove in the jaw, and in the other in actual sockets. Such intermediate, or, as Prof. Huxley would term them, intercalary, forms, tend

materially to bridge over the gap which at first sight appears to exist between reptiles and birds, but which to many palæontologists was far from being impassable, long before the discoveries just mentioned. The amphicœlous character of the vertebræ of *Ichthyornis* presents another most remarkable peculiarity, which is also of high significance. I hear rumours of the discovery of another *Archæopteryx* in the Solenhofen Slates, which is said to present the head in a much more complete condition than that in which it occurs on the magnificent slab now in the British Museum. As yet, I believe, the jaws have not had the matrix removed from them; but should they prove to be armed with teeth, it will to me be a cause of satisfaction rather than surprise, as confirming an opinion which some fifteen years ago[1] I ventured to express, that this remarkable creature may have been endowed with teeth, either in lieu of or combined with a beak.

I must not, however, detain you longer with any of these general remarks, which are, moreover, becoming somewhat egotistic, but will now proceed to the business of this section, in which I hope that more than one paper of great value and interest will be forthcoming.

SECTION D.

BIOLOGY.

OPENING ADDRESS IN THE DEPARTMENT OF ZOOLOGY AND BOTANY, BY PROF. W. H. FLOWER, F.R.S., PRESIDENT OF THE SECTION.

ON the 10th of January, 1778, died the great Swedish Naturalist, Charles Linné, more commonly known as Linnæus, a name which will ever be mentioned with respect and regard in an assembly devoted to the cultivation of the sciences of Zoology and Botany, as whatever may be the future progress of those sciences, the numerous writings of Linnæus, and especially the publication of the "Systema Naturæ," can never cease to be looked upon as marking an era in their development. That work contained a systematic exposition of all that was known on these subjects expressed in language the most terse and precise. The accumulated knowledge of all the workers at zoology, botany, and mineralogy since the world began, was here collected together by patient industry, and welded into a complete and harmonious whole by penetrating genius.

Exactly a century has passed since Linnæus died. What of the progress of the subjects to which he devoted his long and laborious life? This one century is a brief space compared with the ages which have passed since man began to dwell upon the earth, surrounded by living objects, which have, more and more as time rolled on, awakened his curiosity, stimulated his faculties to observe, and impelled him to record the knowledge so gained for the benefit of those to come. How does it stand in comparison with those which preceded it, in the contributions it has thus acquired and recorded?

It may be not without interest in commencing our work at this meeting to cast our eyes back and take stock, as it were, of the knowledge of a hundred years ago, and of that of the present time, and see what advances have been made; to look at the living world as it was known to Linnæus and as it is known to ourselves. The "Systema Naturæ," the last edition of which, revised by the author, was published in 1766, will be a convenient basis for the comparison, but as the subject is one which, even in a most superficial outline, might reach such lengths as would well tire out the most patient of audiences, and absorb time which will be more profitably occupied by the valuable contributions which are forthcoming from other members of the Association, I will merely take a small section of the work, about 100 pages out of the first of the four volumes, those devoted to the first class Mammalia. The comparison of this part is perhaps the easiest, as the contrast is the least striking, and the progress has been comparatively the slowest. The knowledge of large, accessible, and attractive-looking animals had naturally preceded that of minute and obscure organisms, and hence, while in many other departments the advance has altogether revolutionized the knowledge of Linnæus, in the vertebrated classes, especially the one of which I shall now speak, it has only extended and reformed it.

In taking the "Systema Naturæ" of Linnæus, the comparison is certainly carried back somewhat beyond the hundred years which have elapsed since his death, and the brilliant contributions to the knowledge of the Mammalia of Buffon and Daubenton just then beginning to be known, and the systematic compilation of Erxleben (published in 1777), are ignored, but for the present purpose, especially considering the limited time at my disposal, it will be best not to go beyond the actual text of the work in question.

Before considering systematically the different groups into which Linnæus divides the class, I must remark in passing upon what is the greatest, and indeed most marvellous difference between the knowledge of zoology of our time and that of Linnæus. Now we know that the animals at present existing upon the earth are merely the survivors of an immensity of others, different in form, characters, and mode of life, which have peopled the earth through vast ages of time, and to which numerically our existing forms are infinitesimally small, and that the knowledge we possess of an immense number of them, fully justifies the expectation of an enormous further advance in this direction. In the time of Linnæus the existence in any past time of a species having no longer living representatives on the earth, though perhaps the speculation of a few philosophical minds, had not been received among the certainties of science, and at all events found no place in the great work we are now considering.

In the twelfth edition of the "Systema Naturæ" we find the class Mammalia divided into seven orders: I. *Primates*, II. *Bruta*, III. *Feræ*, IV. *Glires*, V. *Pecora*, VI. *Belluæ*, VII. *Cete*. These orders contain forty genera without any intermediate subdivisions. The genera are again divided into species, of which the total number is 220.

The first order, PRIMATES, contains four genera: *Homo*, *Simia*, *Lemur*, and *Vespertilio*.

The vexed question of man's place in the zoological system was thus settled by Linnæus. He belongs to the class *Mammalia*, and the order *Primates*, the same order which includes all known monkeys, lemurs, and bats: he differs only generically from these animals. But then we must remember that the Linnæan genera were not our genera, they correspond usually to what we call families, sometimes to entire orders. So that practically man's position is much the same as that to which, after several vicissitudes, as his separation as an order by Blumenbach and Cuvier, or as a subclass by Owen, he has returned in the systems of nearly all the zoologists of the present day who treat of him as a subject for classification upon zoological and not metaphysical grounds.

Yet since the time of Linnæus the whole science of anthropology has been created. There is certainly an attempt at the division of the species *Homo sapiens* into six varieties in the "Systema Naturæ," but it has scarcely any scientific basis. Zoological anthropology may be said to have commenced with Blumenbach, who, it is interesting to recall as an evidence of the rapid growth of the science, was a contemporary with most of us in this room, for he died as lately as 1840, although his first work on the subject, "De generis humani varietate nativa," was published three years before the death of Linnæus, too late, however, to influence the work we are now chiefly speaking of. The scientific study of the natural history of man is therefore, we may say, but one century old. To what it has grown during that time you are probably aware. Scarcely an important centre of civilisation in the world but has a special society devoted to its cultivation. It forms by itself a special department of the Biological Section of our Association, a department of such importance, that on this occasion no less distinguished a person than a former most eminent president of the whole Association was thought fit to take charge of it. From him you will doubtless hear what is its present scope, aim, and compass. I need only remind you that except the one cardinal point of the zoological relation of man to other forms of life, which Linnæus appears to have appreciated with intuitive perception, all else that you will now hear in that department was not dreamt of in his philosophy.

As might naturally be supposed, apes and monkeys have, for various reasons, attracted the attention of observers of nature from very early times, and consequently Linnæus was able to give rather a goodly list of species of these animals, amounting to thirty-three, but of their mutual affinities, and of the important structural differences which exist between many of them, he seems to have had no idea, his three divisions being simply regulated by the condition of the tail, whether absent, short, or long.

We now know that the so-called anthropoid or man-like apes,

the gorilla, chimpanzee, orang and gibbons, form a group apart from all the others of such importance, that everything related to their history, structure, and habits, has been most assiduously studied, and there is now an immense literature devoted to this group alone. Nothing could better illustrate the advances we have made in a hundred years, than the contrast of our present knowledge of these forms with that of Linnæus. It is true that, as shown in the most interesting story of the gradual development of our knowledge relating to them in the first chapter of Huxley's "Man's Place in Nature," the animal now called gorilla was, without doubt, the pongo, well known to, and clearly described by, our countryman, Andrew Battle, a contemporary of Shakespeare; and that a really accurate and scientific account of the anatomy of the chimpanzee had been published as far back as 1699 by Dr. Edward Tyson, who as the first English comparative anatomist, I am proud to claim as in some sort a predecessor in the chair I have the honour to hold in London, as he is described on the title page of his work as "Reader of Anatomy at Chirurgeons' Hall."

Linnæus was, however, not acquainted with these, and his second species of the genus *Homo*, *H. troglodytes*, and his first of the genus *Simia*, *S. satyrus*, were both made up of vague and semi-fabulous accounts of the animals now known as chimpanzees and orangs, but hopelessly confounded together. Of the gorilla, and what is stranger still, of any of the important genus of gibbons or long-armed apes of South-eastern Asia, he had at the time he revised the "Systema" no idea.

The remaining monkeys, we now know, fall into three very distinct sections: the *Cercopithecidæ* of the Old World, and the *Cebidæ* and *Hapalidæ* of the New, or by whatever other names we may like to designate them. Although members of all three groups appear in the list in the "Systema," they are all confusedly mixed together. Even that the American monkeys belong to a totally different stock from those of the Old World, does not seem to have been suspected.

The genus *Lemur* of Linnæus comprehends five species, of which the first four were all the then known forms of a most interesting section of the Mammalia. These animals, mostly inhabitants of the great island of Madagascar, though some are found in the African continent, and others in some of the Southern and Eastern parts of Asia, constitute a well-defined group, but one of which the relations are very uncertain. At one time, as in the system of Linnæus, they were closely associated with the monkeys. As more complete knowledge of their organisation has been gradually attained, the interval which separates them structurally from those animals has become continually more evident, and since they cannot be placed within the limits of any of the previously constituted orders, it has been considered advisable by some naturalists to increase the ordinal divisions in their behalf and to allow them to take rank as a distinct group, related to the *Primates* on the one hand, and to the *Carnivora* and *Insectivora* on the other. The knowledge of their relations, however, bids fair to be greatly increased by the discoveries of fossil forms lately made both in France and America, some of which seem to carry their affinities even to the *Ungulata*.

Existing upon the earth at present, besides the more ordinary lemurs to which the species known to Linnæus belong, there are two aberrant forms, each represented by a single species. These are the little *Tarsius* of Borneo and Celebes, and the singular *Chiromys*, or Aye-aye, which, though an inhabitant of the head-quarters of the group, Madagascar, and living in the same forests and under the same conditions as the most typical lemurs, exhibits a most remarkable degree of specialization in the structure both of limbs and teeth, the latter being modified so as to resemble, at least superficially, those of the Rodents, a group with which in fact it was once placed. It was discovered by Sonnerat in Madagascar in 1780, two years after the death of Linnæus. The specimen brought to Paris by this traveller was the only one known until 1860. Since that date, however, its native land has been more freely open than before to explorers, and many specimens have been obtained, one having lived for several years in the Gardens of the London Zoological Society.

The history of a name is often not a little curious. Linnæus applied the term *Lemures*, *i.e.*, the departed spirits of men, to these animals on account of their nocturnal habits and ghost-like aspect. The hypothetical continent in the Indian Ocean, supposed to have connected Madagascar with the Malayan Archipelago is called by Mr. Sclater, *Lemuria*, as the presumed original home of the lemur-like animals. Although the steps are not numerous, it might puzzle a classical scholar, ignorant of zoology, to explain the connection between this continent and the Roman festival of the same name.

The fifth animal which Linnæus places in his genus *Lemur*, under the name of *L. volans*, is the very singular creature to which the generic term *Galeopithecus* has since been applied. It is one of those completely aberrant forms, which having no near existing relations, and none yet discovered among extinct forms, are perfect puzzles to systematic zoologists. It is certainly not a lemur, and not a bat, as has been supposed by some. We shrink from multiplying the orders for the sake of single genera containing only two closely allied species; so we have generally allowed it to take refuge among the *Insectivora*, though without being able to show to which of that somewhat heterogeneous group it has any near affinities.

The fourth genus of the *Primates* is *Vespertilio*, comprising six species of bats. This genus has now by universal consent expanded into an order, and one of the best characterised and distinctly circumscribed of any in the class: indeed those who have worked most at the details of the structure of bats, find so much diversity in the characters of the skull, teeth, digestive organs, &c., associated with the modification of the fore-limbs for flight common to all, as almost to entitle them to be regarded rather as a sub-class. Anatomical, as well as palæontological evidence, show that they must have diverged from the ordinary mammalian type at a very far distant date, as the earliest known forms, from the eocene strata, are quite as specialised as any now existing, and no trace has hitherto been discovered of forms linking them to any of the non-volant orders. By the publication within the last few weeks of a valuable monograph on the existing species of the group, entitled "A Catalogue of the Chiroptera in the Collection of the British Museum," by G. E. Dobson, we are enabled to contrast our present knowledge with that of the time of Linnæus. Although the author has suppressed a large number of nominal species which formerly encumbered our catalogues, and wisely abstained from the tendency of most monographists to multiply genera, he describes four hundred species, arranged in eighty genera: nearly double the number of species, and exactly double the number of genera, of the whole class Mammalia in the "Systema Naturæ," and these Dr. Günther remarks in his preface are probably only a portion of those existing. The small size, nocturnal habits, and difficulty of capture of these animals, are sufficient reasons for the supposition that there are still large numbers unknown to science. In the list of Linnæus, the first primary group of Dobson, the *Megachiroptera*, now containing seventy species, is represented by a single one *V. Vampyrus*, obviously a *Pteropus*, to which the bloodthirsty habits of the fabulous vampyre are attributed, but which is not absolutely identified with any one of the known species. The other species described by Linnæus can almost all be identified with bats at present well known.

A curious example of the results of basing classification upon a few, and those somewhat artificial characters, is afforded by one of the true bats, now called *Noctilio leporinus*, though admitted by Linnæus to be "*simillimus vespertilionibus similiter pedibus alatus*," being separated from the others, not only generically, but even placed in another order, that of the *Glires* or Rodents, because it did not, or was supposed not to, fall under the definition of the order *Primates*, which begins "*Dentes primores incisores superiores IV. paralleli.*' In reality this bat has four upper incisors, but the outer ones are so small as to have been overlooked when first examined. But even if this were not so no one would now dream of basing an animal's position upon such a trivial character when opposed to the totality of its organization and habits.

The characters of the incisor teeth are placed in the first rank in the definitions of all the orders in the "Systema Naturæ," and hence the next order called BRUTA, characterized by "*dentes primores nulli superius aut inferius*," contains a curious mixture of heterogeneous animals, as the names of the genera *Elephas*, *Trichechus*, *Bradypus*, *Myrmecophaga*, *Manis*, and *Dasypus* will indicate. In contains, in fact, all the animals then known comprised in the modern orders of *Proboscidea*, *Sirenia*, and *Edentata*, together with the walrus, one of the *Carnivora*. The name *Bruta* has been revived for one of these orders, that more generally called *Edentata*, but I think very inappropriately, for it was certainly not equivalent, and if retained at all, should rather belong to the Proboscidea, as *Elephas* stands first in the list of genera, and was probably in the mind of Linnæus when he assigned the name to the group.

It is curious to find that the striking differences between the African and the Indian elephants, now so well understood by every beginner in zoology, and all the facts which have already been accumulated relating to the numerous extinct forms of Proboscideans, whether Mammoths, Mastodons, or Dinotheria, were quite unknown to Linnæus. One species only, *Elephas maximus*, represented in the zoology of a hundred years ago, was all that was known of the elephants or elephant-like animals.

The genus *Trichechus* of this edition exhibits a very curious phase of zoological knowledge. It contains two species. (1) *T. rosmarus*, the Walrus, now known to be a modified seal, and therefore a member of the Linnæan order Feræ, and (2) *T. manatus*, a name under which were included all the known forms of Manatees and Dugongs, in fact the whole of the modern order *Sirenia;* animals widely removed in all essential points of their organisation from the walrus, with which they are here generically united. Their position, however, between the elephant on the one hand and the sloths on the other, is far better than their association with the Cetacea, as in Cuvier's system, an association from which it has been most difficult to disengage them, notwithstanding their total dissimilarity, except in a few external characters. Although the discovery of many fossil forms has done much to link together the few existing species and to show the essential unity of the group, it has thrown no light upon their origin, or their affinities to other mammals. They still stand, both by their structure and their habits, a strangely isolated group, and it baffles conjecture to say whence they have been derived, or how they have attained their present singular organisation.

The remaining genera of the Linnæan order *Bruta* constitute the group out of which Cuvier, following Blumenbach, formed his order *Edentata*, a name certainly not happily chosen for a division which includes species like the great armadillo, having a larger number of teeth than any other land mammal, but which, nevertheless, has been so generally adopted, and is so well understood, that to attempt to change it would only introduce an element of confusion. Four out of five of the principal modifications of form in the group at present known, are indicated by the four Linnæan genera, *Bradypus* or Sloth, *Myrmecophaga* or Ant-eater, *Manis* or Pangolin, and *Dasypus* or Armadillo. The advances during the century have consisted in the accumulation of a great mass of details respecting these groups, the addition of a fifth and very distinct existing form, the *Orycteropus* or Cape Anteater, and the discovery of numerous and very remarkable extinct forms, such as the megatheriums and glyptodons of South America, so fully known by their well-preserved osseous remains. There is, however, still much to be done in working out the real relationship of the somewhat isolated members of the order, if it be a natural order, both to each other, and to the rest of the Mammalia, from which they stand widely removed in many points of organisation.

The third order of Linnæus, FERÆ, contained all the then known animals, which, with whatever diversities of general structure, agreed in their predatory habits, and possessed certain general characters of teeth and claws to correspond, though the terse definition of "*Dentes primores superiores sex, acutiusculi, canini solitarii*," is by no means universally applicable to them. This order was broken up by Cuvier into the orders Carnivora and Insectivora, and the genus *Didelphys*, included in it by Linnæus, has been since by universal assent removed to another group.

The first six genera belong to the very well-defined and probably natural group now called *Carnivora*. The one placed at the head of the list, *Phoca*, is equivalent to the large and important modern sub-order *Pinnipedia*, the walrus, however, though essentially a seal, having been, as before mentioned, relegated by Linnæus to another order on account of its aberrant dentition. But three species are recorded in the genus. *P. ursina*, the Sea-bear of the North Pacific (now *Otaria ursina*), *P. leonina*, founded on Anson's sea-lion, now commonly called the elephant seal, or sea-elephant (*Macrorhinus proboscideus*, or more properly *leoninus*), and *P. vitulina*, the Common Seal.

The terrestrial sub-order of Carnivora is represented by five genera. (1) *Canis*, including the dog, wolf, hyæna, fox, arctic fox, jackal, &c. (2) *Felis*, with only six species, but still one of the few Linnæan genera, which covers exactly the same ground as at present in the opinion of the majority of zoologists, although it may be mentioned as an example of the tendency towards excessive and unnecessary multiplication of generic names which exists in some quarters, that it has been divided into as many as fourteen. (3) *Viverra*, a heterogeneous group, containing ichneumons, coatis, and skunks, animals belonging to three very distinct families, according to modern ideas. (4) *Mustela*, a far more natural group, being nearly equivalent to the modern family *Mustelidæ*; and, lastly, a very comprehensive genus, *Ursus*, consisting of *U. meles*, the Badger, *U. lotor*, the Raccoon, *U. luscus*, the Wolverene, and all the true bears known, comprised in the single species *U. arctos*. Many interesting forms of Carnivora, as *Cryptoprœta*, *Proteles*, *Eupleres*, *Ailurus* and *Ailuropus*, have no place in the Linnæan system, being comparatively modern discoveries. The very recent date (1869) at which the last-named remarkable animal was made known to science by the enterprising researches of the Abbé David into the fauna of Eastern Thibet, gives hope that we may not yet be at the end of the discovery of even large and hitherto unsuspected forms of existing mammals.

Next in the Linnæan system comes the genus *Didelphys*, constituted for the reception of five species of American opossums. This is a very interesting landmark in the history of the progress of the knowledge of the animal life of the world, as these five opossums, forming a genus in the midst of the order Feræ, were all that was then known of the great sub-class *Marsupialia*, now constituting a group entirely apart from the ordinary members of the class. It is difficult now to imagine an animal world without kangaroos, without wombats, without phalangers, without thylacines, without dasyures, and so many other familiar forms, and yet such was the animal world known to Linnæus. It is true that a species of kangaroo from one of the islands of the Austro-Malayan Archipelago was described as long ago as 1714 by De Bruijn, who saw it alive at the house of the Dutch governor of Batavia, and that Captain Cook and Sir Joseph Banks saw and killed kangaroos on the east coast of Australia in 1770, and had published figures and descriptions of them in 1773, or five years before the death of Linnæus, but the work we are now considering contains no traces of knowledge of the existence of such a remarkable and now so well-known animal.

The three remaining genera of FERÆ, *Talpa*, *Sorex*, and *Erinaceus*, contained all the known species of the present order INSECTIVORA, which now embraces many and very varied forms, quite unsuspected a century ago, and to which it is probable that others will be added by the time the exploration of the animal products of the world is completed.

The fourth order, GLIRES, has remained practically unchanged to our day, although the name *Rodentia* has generally superseded that bestowed upon it by Linnæus. The five genera of the "Systema Naturæ," *Hystrix Lepus*, *Castor*, *Mus*, and *Sciurus*, have been vastly increased, partly by subdivision and partly by the discovery of new forms. *Noctilio* is, as before mentioned, removed to the Chiroptera, but its loss is well compensated for by *Hydrochœrus*, the well-known Capybora, the largest existing member of the group, which in the Linnæan system is placed among the Belluæ, in the same genus with the pigs.

The fifth Linnæan order, PECORA, is a fairly natural group, equivalent to Cuvier's *Ruminantia;* but it is no longer considered of the value of an order, since the animals composing it have now been shown to be as closely related to certain of those belonging to the next order as they are to each other. The first genus, *Camelus*, contains both the American lamas and the Old World camels, the demonstration of the common origin and close affinities of which has been one of the important results of the recent discoveries in the palæontology of the Western continent. In the next genus, *Moschus*, were placed the well-known musk deer of the highlands of Central Asia, and two small African antelopes, which have no special affinity with it. The subsequent inclusion in the same genus of the small chevrotains (*Tragulinæ*), which was very natural at the time, as they agree perfectly with the musk in the absence of horns and the presence of large canine tusks, by which artificial characters the genus was defined by Linnæus, was one of those unfortunate associations which has greatly retarded the progress of knowledge of the true affinities of the group. Judging by the popular works on Zoology, it is still as difficult to apprehend that a chevrotain is not a musk deer, as it is that a manati is not a cetacean; both errors of the same kind, if not quite so gross, as that of regarding a whale as a fish, or a bat as a bird. The genus *Cervus* contains six species of true deer, including the moose, reindeer, red deer, fallow and roe, associated with the giraffe.

The twenty-one species at that time recognised of the great group of hollow-horned Ruminants are distributed quite artificially in three genera, *Capra*, *Ovis*, and *Bos*. Though subsequent investigations have greatly increased the number of species known, we are still in much uncertainty about their mutual affinities and generic distinctions. Being a group of comparatively modern origin, and only just attaining its complete development, variation has chiefly affected the less essential and superficial organs, and the process of extinction of intermediate forms has not operated sufficiently long to break it up into distinctly separated natural minor groups, as is the case with many of the older families, which yield, therefore, far more readily to the needs of systematic classification, especially as long as the extinct forms are unknown or ignored.

The sixth order of land mammals, BELLUÆ, corresponding to the *Pachydermata* of Cuvier, contains what is now known to be a heterogeneous collection, viz., the horses, the hippopotamus, the pigs, rhinoceros, and the rodent capybara. The abolition of these two last orders and the entire rearrangement of the ungulate mammals into two different natural groups, now called *Artiodactyla* and *Perissodactyla*, first indicated by Cuvier in the "Ossimens Fossiles," from the structure of the limbs alone, and afterwards confirmed by Owen from comparison of every part of the organisation, has been one of the most solid advances made in our knowledge of the relations of the mammalia during the present century.

The past history of this, as of so many other groups of vertebrated animals, has been brought to light in an unexpected manner by the wonderful discoveries of fossil remains made during the last ten years in the Rocky Mountains of America, discoveries the importance of which will only be fully appreciated when the elaborate and beautifully illustrated work which Prof. Marsh has now in progress is completed.

The last Linnæan order, CETÆ, is exactly conterminous with the order so named, or rather more generally modified to *Cetacea*, in the best modern systems, for Linnæus did not commit the error of Cuvier and others, of including the Sirenia among the whales. His knowledge of the animals composing the group was necessarily very imperfect, indeed it is only within the last few years, especially since the impulse given to their study by Eschricht of Copenhagen, that the great difficulties which surround the investigation of the structure and habits of these denizens of the open sea have been so far surmounted that we have begun to obtain clear views of their organisation, affinities, and geographical distribution.

Two most remarkable forms of mammals, so abnormal in their organisation as now to be generally considered deserving the rank of a distinct sub-class, the *Echidna* and *Ornithorhynchus*, were first made known to science in 1792 and 1799 respectively, and consequently have no place in the "Systema Naturæ." The very recent discovery of a third form to this group, or at least a very striking modification of one of the forms, the large New Guinea echidna (*Acanthoglossus bruijnii*), is the last important acquisition to our knowledge of the class.

In this brief review of the progress of one small section of one branch of zoological knowledge it will be seen that it is chiefly of systems of arrangement, of classification, and of names that I have been treating. By many biologists of the present day these are looked upon as the least attractive and least profitable branches of the subject. The interest of classification, though it has lost much in some senses by the modern advances of scientific biology, has, however, gained vastly in others. The idea that has now, chiefly in consequence of the writings of Darwin, taken such strong hold upon all working naturalists—the idea of a gradual growth and progressive evolution, and therefore genetic connection between all living things—breaks down the artificial barriers which zoologists raise around their groups, and shows that such names as *species*, *genera*, *families*, *orders*, &c., are merely more or less clumsy attempts to express various shades of differences among creatures connected by infinite gradations, and in this sense destroys the importance attached to them by our predecessors. On the other hand, it immensely increases the interest contained in the word relationship, as it implies that the word is used in a real and not, as formerly, in a metaphorical sense. There is a kind of classification, such as we might apply to inanimate substances or manufactured articles. We may say, for instance, that a tumbler, a wine-glass, and a tea-cup are more closely related to each other than either one is to a chair or a table, and that they might be formed into one group, and the last-named objects be placed in a second. This kind of classification is certainly useful in its way for methodical arrangement and descriptive purposes. It is the kind of arrangement which Linnæus and his contemporaries applied to animals. It is, however, a very different classification from that which supposes that the members of a group having common essential characters are descended from a common ancestor, and have gradually, by whatever cause or means, become differentiated from other groups. On this view a true classification, if it could be obtained, would be a revelation of the whole secret of the evolution of animal life, and it is no wonder that many are willing to devote so large a share of their energies to endeavour to attain it.

The right application of the principles of nomenclature, first clearly established by Linnæus, to the groups we form is, again, by no means to be despised, as laxity and carelessness in this respect are becoming more and more the greatest hindrances to the study of zoology. The introduction of any new term, especially a generic name, and indeed the use of an old one by any person whose authority carries weight, has an appreciable effect upon the progress of science, and should never be done without a full sense of the responsibility incurred. All beginners are puzzled and often repelled by the confused state of zoological nomenclature to an extent to which those who have advanced so far as only to care for the things, and to whom the actual names by which they are called are comparatively indifferent, have little idea. Those whose special gift or inclination leads them to the pursuit of other branches of biology, as morphology, physiology, embryology, &c., must have definite names for the objects they observe, depict, or describe, and are dependent upon the researches of the systematic zoologist for supplying them, and should not neglect to take his counsel, otherwise much of their work will lose its value.

Several times has the British Association thought this a worthy subject for the consideration of its members, and through the instrumentality of a committee of working naturalists drew up in 1842 an excellent code of regulations and suggestions on the subject of zoological nomenclature. These rules were revised and reprinted in 1865, and in accordance with a resolution adopted at the last annual meeting at Plymouth they have been again republished at the cost of the Association during the present year. The mere issue of such rules must have had a beneficial effect, as they have undoubtedly been a guide to many careful and conscientious workers. Unfortunately there are no means of enforcing them upon those of a different class, and there is still something wanting short of enforcing them, which possibly may be within the power of the Association to effect. In the administration of the judicial affairs of a nation, besides the makers of the laws, we have an equally essential body to interpret or apply the law to particular cases—the judges. However carefully compiled or excellent a code of regulations may be, dubious and difficult cases will arise, to which the application of the law is not always clear, and about which individual opinions will differ. The necessary permission given in the Association rules to change names which are either "glaringly false," or not "clearly defined," opens the door to considerable latitude of private interpretation. As what we are aiming at is simply convenience and general accord, and not absolute justice or truth, there are also cases in which the rigid law of priority, even if it can be ascertained, requires qualification, and other cases in which it may be advisable to put up with a small error or inconvenience to avoid falling into a larger one. I may name such cases as the propriety of reviving an obsolete or almost unknown name for one which, if not strictly legitimate, has been universally accepted, or the retention of a name when already applied to a different genus, instead of the institution of another in its place. For instance, should the name *Echidna*, by which the well-known monotrematous mammal is known in every text-book and catalogue in every language, be superseded by *Tachyglossus*, because the former name had previously been applied to a genus of snakes? or should the chimpanzee be no longer called *Troglodytes* lest it should be confounded with a wren? Should *Chiromys* be discarded for *Daubentonia*, *Trichechus* for *Odobenus*, and *Tapirus* for *Hydrochœrus?* Should the Java slow lemur be called *Loris*, *Stenops*, or *Nycticebus?* Should Sowerby's whale be placed in the genus *Physeter*, *Delphinus*, *Delphinorhynchus*, *Heterodon*, *Diodon*, *Aodon*, *Nodus*, *Ziphius*, *Micropterus*, *Micropteron*, *Mesodiodon*, *Dioplodon*, or *Mesoplodon*, in all of which it may be found in various systematic lists? Should one of the largest and best known of the Cetaceans of our seas be called *Balænoptera musculus*, *Physalus antiquorum*, or *Pterobalæna communis*, all names used by authors of high

authority? Should the smallest British seal be called *Phoca hispida*, *fœtida*, or *annellata*?

I might go on indefinitely multiplying instances which will be answered differently by different naturalists, the arguments for one or the other name being often nicely balanced. What is wanted, therefore, is some kind of judicial authority for deciding what should in future be used. If a committee of eminent naturalists, selected from various nations and divided into several sections according to the subjects with which each member is most familiar, could be prevailed upon to take up the task of revising the whole of our existing nomenclature upon the basis of the laws issued by the Association in 1842, occasionally tempering their strictly legal decisions with a little discretion and common sense, and with a view, as much as possible, of avoiding confusion, and promoting general convenience; and if the working zoologists of the world generally would agree to accept the decisions of such a committee as final, we should dispose of many of the difficulties with which we are now troubled. There seems to me no more reason why the nomenclature of such a committee, if it were composed of men in whose judgment their fellow-workers would have confidence, should not be as universally accepted as is the nomenclature of the last edition of the "Systema Naturæ" of Linnæus. We have agreed not to look beyond that work for evidence of priority, and why should we not agree in the same way to accept decisions which would probably be arrived at with even fuller knowledge and greater sense of responsibility?

Whether this suggestion will be received with favour or not it appeared to me that it was one not inappropriate for the consideration of this section which has already dealt with the question in a manner so advantageous to science, and also for this year, which has witnessed the hundredth anniversary of the death of the great teacher of systematic zoology.

Our knowledge of the living inhabitants of the earth has indeed changed since that time. Our views of their relations to the universe, to each other, and to ourselves, have undergone great revolutions. The knowledge of Linnæus far surpassed that of any of his contemporaries; but yet of what we now know he knew but an infinitesimal amount. Much that he thought he knew we now deem false. Nevertheless, some of the oldest words to be found in all his writings contain sentiments which still claim a response in the hearts of many. Although we are less accustomed to see such words in works of science, that is no proof that their significance has been impaired by the marvellous progress of knowledge. With the words which Linnæus selected to place at the head of his great work I will conclude—

> "O Jehova,
> Quam ampla sunt tua opera!
> Quam sapienter ea fecisti!
> Quam plena est terra possessione tua!"

NOTES

THE International Congress of Meteorology, to be held in Paris from August 24 to 28 next, at the Trocadéro, will discuss a long series of questions having an important bearing on the progress of meteorology, and especially on combined action on the part of the meteorologists of various countries. Sixteen subjects are down for discussion relating to the study of storms in Europe and America, the means of carrying on and recording meteorological investigations on a uniform plan, the origin and propagation of cyclones, meteorology and aeronautics, terrestrial magnetism, sun-spots and meteorology, influence of the configuration and nature of soil, and other physical conditions on climate, earthquakes, the measures to be adopted in observatories to hasten the progress of meteorology &c. This is certainly a comprehensive programme, and we trust there will be a good attendance of competent meteorologists of all nations, and that some good practical results will be the outcome of the meeting.

WE notice that Prof. Fuller has resigned the professorship of mathematics at Aberdeen, which he has held with so much distinction. All of the long list of Senior Wranglers who have come from the University of Aberdeen within the last twenty-five years have been his pupils. Prof. Fuller was tutor of Peterhouse before his appointment to Aberdeen. The chair will probably be filled up in September by the University Court.

THE *Journal Officiel* has published the dates of three new congresses to be held at the Trocadéro and Tuileries:—Weights and Measures, September 2, 3, 4; Silk-culture, September 5, 6, 7, 9, 11; Legal Medicine, August 11, 13, 14.

WE are informed that a course of six lectures on meteorology will be given under the auspices of the council of the Meteorological Society, commencing in October next. The subjects of the lectures will be:—"The Nature and Physical Properties of the Atmosphere;" "Air Temperature, its Distribution and Range;" "Atmospheric Pressure, Wind, and Storms;" "Clouds and Weather Signs;" "Rain, Snow, Hail, and Electricity;" and "The Nature, Methods, and General Objects of Meteorology." It is intended that these lectures shall give a concise account of the present state of knowledge on the above subjects. The lectures will be open to the public, admission being by ticket, to be obtained at the office of the Society, 30, Great George Street, Westminster, S.W. Further particulars, giving full information as to the time, place, &c., will be duly announced.

SCIENTIFIC study does not yet appear to have attracted a superfluity of women, to judge by the numbers of candidates at the Cambridge Higher Local Examinations recently held. Only about thirty out of 500 took the science subjects; twenty-one took botany, one failed, and three obtained distinction; twenty-six geology and physical geography, of whom two failed, and seven were distinguished; seven geology, one failed, three distinguished; nine chemistry, three failed, none distinguished. Ten of the science candidates sat at Cambridge, and among them they gained ten out of fourteen of the distinctions given. Miss E. M. Clarke, of Cambridge, was distinguished in geology, zoology, and botany, and passed in chemistry. Mathematics got only twenty-three candidates, of whom four failed; only two, however, were placed in the first class (being Cambridge students), and two in the second. We are glad to learn that two new subjects are to be set in the science group next year, namely, physics and physiology, the latter so much needed in all girls' schools. Also, students will be allowed to take this group without having to pass Group A (literature and history) first, although it will be required for a full certificate.

SIR SAMUEL BAKER, in a letter to a contemporary, advocates the establishment of a botanical garden in Cyprus, similar to that in Ceylon, under the charge of a competent official, by whom experiments will be made, and the trees most suitable for the climate and varying altitudes of mountain ranges be selected.

A PERUVIAN newspaper, the *Bolsa*, we learn from the *Colonies*, says that extraordinary phenomena have been observed in connection with the "Corpuna" volcano in the province of Castilla, which have caused great alarm among the population. The immense banks of snow which have crowned its summit from time immemorial have suddenly melted away with such rapidity as to cause torrents to rush down the sides of the mountain, washing out immense quantities of stones and earth. The river below, being unable to contain the great body of water so suddenly added to it, overflowed its banks, causing great damage and distress. A great chasm or lateral crater next opened on one side, throwing out volumes of smoke and steam as well as tongues of flame, which were distinctly visible at night, accompanied with loud subterranean rumblings. It had never been supposed that the Corpuna was or could be a volcano. and there is no tradition that it was ever in a state of eruption, Nor within the memory of man has its crown of snow ever been absent.

THE British Medical Association concluded its meeting at Bath on Friday. The Association meets next year at Cork, Dr. O'Connor being the president elect.

EXPERIMENTS have been made at Paris with the telephone between the Exhibition building and Versailles, and they proved very successful. It is intended to make use of the telephone during the great military manœuvres.

THE Paper Exhibition which we intimated some time ago was to be held in Berlin is now opened, and an instructive and interesting account of the variety of objects exhibited—from flimsy to paper carpets, chairs, and even boats—will be found in the *Times* of the 13th. Both the articles manufactured and the materials, chemical and other, connected with the manufacture of paper, are exhibited, and judging from the description, the exhibition althogether must be at least as attractive as the Caxton Exhibition of last year. One of the principal exhibitors is Prince Bismarck, who is a partner in a large firm at Varzin; one of his specialties is paper slips for the Morse telegraph apparatus. The following interesting statistics are given by the *Times*' Correspondent from the Catalogue :—

	Number of Inhabitants.	Kilos consumed.	Kilos per head.
United States	39,000,000	535,000,000	14
Germany	43,000,000	244,000,000	6
England	33,000,000	168,000,000	5
France	37,000,000	138,000,000	3·6
Austria-Hungary	36,000,000	92,000,000	2·5
Russia	27,000,000	67,000,000	0·9
Italy	28,000,000	38,000,000	1·4
Scandinavia	6,000,000	3,000,000	0·5
Belgium	5,500,000	27,000,000	5·1
Switzerland	2,500,000	17,000,000	6·3

According to inscriptions put up in the hall and illustrated by paste-board cubes of different size, 600,000,000 men employ Chinese paper, while 366,000,000 use the European and 130,000,000 the Arabian article; 24,000,000 write on leaves, bark, and wood, 280,000,000 dispensing with writing and reading, and consequently taking no interest in this enlightened exhibition.

THE excursionists who went to the Boulonnais last week under the auspices of the Geologists' Association, led by Prof. Morris, seem to have had a good time of it. Their intention having been communicated to M. A. Huguet, Senator, Maire of Boulogne, he convoked the local geologists, the members of the Société Académique de Boulogne, the Société Médicale, the committees of the Public Library and of the Museum, and invitations were at the same time sent to the Presidents of the Geological Societies of Paris, Lille, &c., to meet their scientific brethren from across the Channel and give them a proper welcome on this the first occasion of English geologists in any number visiting France. Among those assembled to meet the excursionists on their arrival at Boulogne were M. Edmond Pellat, ex-president of the French Geological Society, Dr. Ch. Barrois, Vice-president of the North of France Geological Society, Prof. Giard of the Zoological Laboratory at Wimereux, the British Vice-Consul and other persons of note. The Maire bade the party welcome, and hoped he would have the pleasure of welcoming other deputations of scientific inquirers. Indeed the occasion seems to have assumed somewhat of an international character, and we should not be surprised if the Maire of Boulogne has to welcome many such deputations. Perhaps, should the North of France Geological Society organise an excursion to the London Basin, the Geologists Association may succeed in getting the Lord Mayor to return the pleasant compliment paid the English geologists by the civic chief of Boulogne; a Mansion House dinner might even be possible.

M. BISCHOFSHEIM, the well-known generous Parisian banker, having recently visited Montsouris Naval Observatory, and found the canvas roof of the equatorial house in wretched condition, Admiral Mouchez told him, in answer to his inquiry, that the budget of the observatory was not rich enough to meet an expense of 50*l*. required for the construction of a comfortable zinc cover. Next morning Admiral Mouchez received a cheque for 120*l*. from his visitor of the previous evening.

WE believe it is deeply regretted in France that M. André and M. Angot, the two French astronomers sent out to America to observe the recent transit of Mercury, did not stay to observe the solar eclipse of July 29, although the two phenomena were visible from the same place. M. André is now in Lyons, and M. Angot arrived in Paris almost on the day when the telegram announced the detection of Vulcan by Prof. Watson.

THE new hotel of the Paris Geographical Society is fast approaching completion, and the date for the opening will be determined soon.

WE regret to state that M. Cochery, the director of the French Postal Telegraph Department, has announced his intention of charging the several communes receiving the daily telegrams of the Agricultural Service a sum of 4*l*. a year. M. Mascart, the new director of the Central Bureau, has obtained the postponement of this step for a month. If M. Cochery carries his resolution into effect it is pretty certain that the greater number of rural communes will refuse to pay, and the organisation which M. Leverrier had so well organised will be thrown into a state of disorganisation less than a year after his death. It is certain that the Meteorological Congress, which is to meet at the Trocadéro ten days hence, will interfere and lay the case before the public.

M. BARDOUX has sent to the prefects of the several departments of France a circular, asking them to collect information on the resources, working, and composition of the meteorological commissions established by Leverrier. The minister intends to give to these boards a uniform organisation.

IT is stated in the French papers that Mr. Edison is to have no reward whatever at the Paris Exhibition for his phonograph. The reasons alleged for this apparent denial of justice are somewhat amusing. The jury of the class of instruments of precision declared that the phonograph could not be considered as at all an instrument of precision, but merely a toy; consequently they sent it to the class of telegraphy to be rewarded. But the telegraphists replied that it was of no use whatever in telegraphy, and refused to examine it. The consequence is that the most wonderful invention, probably, in the Exhibition, will be passed by unmentioned and unrewarded.

ON Friday, August 9, the Société Française d'Hygiène held a banquet at the Continental Hotel, Paris, for the reception of the Sanitary Institute of Great Britain. Dr. Ricord was in the chair, assisted by M. de Lesseps and Anatole de la Forge, the Director of the Press Department in the Home Office. The toast of the Sanitary Institute was replied to by Mr. Chadwick, who handed to the Société Française d'Hygiène a diploma of affiliation signed by the Duke of Northumberland and Dr. Richardson. Some members of the English Ladies' Sanitary Association were also present at the banquet.

IT is not generally known, we are told by the *China Mail* of Hongkong, that official rank is, to a certain extent, hereditary in China. Thus, when an officer of the first rank dies—the four grand secretaries, viceroys, and chief presidents of the "boards" at Peking, for instance—his sons inherit the "full fifth" rank, and are entitled to commence their public career as *Langchung*, or junior lord, of one of the boards. The sons of officers of the "full-second" rank—such as vice-presidents of the boards and governors—may enter public life as assistant

secretaries, with the "half-fifth" rank. The sons of officers of the "half-second" rank become under-assistants, with "full-sixth" rank. The sons of officers of the third rank obtain the honorary degree of bachelor of arts, carrying the seventh rank. The sons of deceased officers of lower grades inherit no rank.

THE thirty-ninth anniversary meeting of the Royal Botanic Society was held in the Gardens, Regent's Park, on Saturday, Mr. James Heywood, F.R.S., in the chair. The annual reports of the council, auditors, and secretary were read. From these reports it appears that the affairs of the society are in a satisfactory state; the receipts in each of the several items had exceeded those of 1877, the balance being some 600*l*. better. The number of new Fellows elected was 112. Four hundred and eighty-one free students' orders for terms of two to six months each had been issued, including sixty-three to artists. The number of cut specimens given to students, professors, and teachers at the several medical and other schools was 63,414—an increase of 20,000 over last year, and 40,000 more than in 1871. The usual exchange of plants and seeds has been maintained with vigour; valuable contributions to the Society's collections were received from correspondents, including the Botanic Gardens of South Australia, Mauritius, Dublin, &c., and also from the Royal Gardens, Kew.

THE additions to the Zoological Society's Gardens during the past week include two European Lynx (*Felis lynx*) from Norway, presented by Major Chadwick; a Hobby (*Hypotriorchis subbuteo*), British Isles, presented by Mr. Howel Scratton; a Solitary Thrush (*Monticola cyanea*), European, presented by Mr. W. Verner; a Common Marmoset (*Hapale jacchus*), a Weeper Capuchin (*Cebus capucinus*), three Bluish Finches (*Spermophila cærulescens*) from Brazil, a Coati (*Nasua nasica*), a Common Boa (*Boa constrictor*), a Common Teguexin (*Teius teguexin*) from South America, a Red and Blue Macaw (*Ara macao*) from Central America, deposited; a Black-footed Penguin (*Spheniscus demersus*) from South Africa, two Common Kingfishers (*Alcedo ispida*), British Isles, purchased; a Wapiti Deer (*Cervus canadensis*), born in the Gardens; a Black-crested Cardinal (*Gubernatrix cristatella*), two Talpacoti Ground Doves (*Chamæpelia talpacoti*), bred in the Gardens.

THE NORWEGIAN NORTH ATLANTIC EXPEDITION

THE Expedition left Hammerfest on July 13 on its trip westwards. The depths sounded on the following days were not great, the greatest being 1,440 fathoms in 72° 16′ N. lat. and 8° 9′ E. long. On the 17th, late in the evening, we unexpectedly met the ice of the Greenland Arctic current, in 73° 10′ N. lat. and 3° 22′ W. long., and were obliged to turn eastwards and northwards. Our next cross section commenced in 75° 16′ N. lat. and 0° 54′ W. long., and went along the 75th parallel to a point north-east of Bear Island. On the westernmost point we had a depth of 1,985 fathoms, but later only smaller depths. The bank west of Bear Island lies much more easterly and nearer this island than shown in the charts, there being a depth of 1,100 fathoms in the place where the French Expedition with *La Recherche* in 1839 gives 259 fathoms. The weather was in the beginning favourable, but under the ice we had strong northerly winds with a temperature of 2° C. and a heavy swell from the south-east. Having passed the meridian of Bear Island the temperature of the water fell to 0·2° C. on the Spitzbergen Bank. From our last sounding and dredging station north-east of Bear Island we sailed down to the east side of the island and stopped outside the south-east side, but the heavy wind and sea did not allow us to go on shore. With the glass we saw distinctly the Russian hut and its environs, but were not able to see our flag, which we had planted by the Dutch port, nor any column or cairn which could show us that the Dutchmen had been there. At 10 P.M. on July 23 we made sail for Norway, and with a fair but rather heavy gale and storm the *Vöringen* went on, heavily rolling, till we, twenty-four hours afterwards, made the Norwegian coast in thick rainy weather. At 4 A.M. on the 24th we dropped our anchor in Hammerfest.

Our soundings show that there is a sort of ridge 1,200–1,300 fathoms deep, between Bear Island and Jan Mayen. The trawl has brought up from the ice-cold water in these depths many rare and several new fishes, particularly of the genus Lycodes. A good many other new animals have been secured by our zoologists. The line of 0° C. lies in our last two cross-sections still at a depth of 500 fathoms. In the eastern part of our sea, the boundary line of the polar current, where 0° is to be found is less than 30 fathoms, and the surface water is less than 5°, lies in lat. 72½° N., long. 6° E., and in lat. 75° N., long. 7½° E. North and east of Bear Island the ice-cold Spitzbergen current runs southward over a very shallow bottom, the depths being only some 20 fathoms. The border of the Greenland Arctic current shows the same phenomenon as that observed in our northern fjords, viz., a minimum of temperature in, say, 40 fathoms depth, a second maximum about 0° C. in, say, 100 fathoms, and the absolute minimum of − 1·4° at the sea bottom.

We are now fitting out for our last trip, to the sea west of Spitzbergen, and expect to be ready to sail on the 30th.

At this moment we have news from the Dutch expedition, whose commander has left a letter, sent us from Vardö. He tells us that they made Jan Mayen on the east side but were not able to land in the heavy sea. From Jan Mayen they proceeded along the edge of the ice to Hackluyt's Headland, North Spitzbergen, which they reached on June 19. North of Spitzbergen they spent some fourteen days, and went as far east as to the Verlegin Hook. Thence they sailed southwards, called at Kobbe Bay, and found our mail at Bear Island, but were obliged to leave that place in a hurry, the wind being rather strong. Their letters home have probably been taken by a Norwegian fisherman off Vardö. Prof. Nordenskjöld passed the North Cape some days ago.

Hammerfest, July 27 H. MOHN

THE ECLIPSE OF THE SUN

ON another page we print an article, just received from Mr. Lockyer, on the recent eclipse, which, from its title and date, it will be seen was written before the event. The following telegrams from the *New York Tribune* of July 31 will perhaps enable our readers, in the meantime, to form a more complete idea of the results achieved.

A telegram to the *Tribune* from Lebanon, Mo., July 30, states that the Fort Worth party of observers, consisting of L. Waldo and R. W. Willson, of Harvard University, Prof. J. K. Ries and W. H. Pulsifer, of St. Louis, and Mr. F. E. Seagrave, of Providence, R. I., had fine weather for their observations, and met with general success. The four contacts were observed both with and without spectroscopes. The reversion of the spectral lines at totality, and the corona and its spectrum were studied, and five photographs, two of them polariscopic, were secured during totality. A number of sketches by local observers, for extent and form of corona, were made. The observers stationed by this party at McKinney, Allen, Cleburne, Waco and Dallas, were also generally successful in observing the duration of totality.

The following official telegrams were received at the U.S. Naval Observatory from the Naval Professors who were in charge of parties sent out to observe the eclipse :—

"*Las Junta, Col., July* 29.

"Good observations of the eclipse at Las Junta. Complete set of photographs. "ASAPH HALL"

"*Creton, W.T., July* 29

"Sky cloudless and observations perfectly successful. Six photographs of corona. Four polariscope photographs of corona and a fine drawing obtained. No ultra violet spectrum visible during totality. "W. HARKNESS"

"*Central City, Col., July* 29

"Whole eclipse perfectly observed. I find no Vulcan as large as sixth magnitude. Hastings finds consistent tangential polarisation. Drawings and photographs of corona. Diffraction shade bands observed. "E. J. HOLDEN"

"*Separation, W.T., July* 29

"Observations here very successful. Saw wings of light, supposed to be zodiacal light, extending 6° on each side of the moon in the direction of the ecliptic. Commander Sampson, U.S.N., found no dark lines in continuous spectrum of corona. Line 1,474 seen near sun's limb. No bright lines visible a few seconds after totality. "S. NEWCOMB"

"*Pike's Peak, Col., July* 29

"Fair weather after a week's storm. Observations successful in a marvellously clear sky. Corona resembling zodiacal light followed in one direction twelve diameters from the sun. "S. P. LANGLEY."

"Eclipse successfully observed at Dallas, Texas. All four contacts satisfactory. No inter-Mercurial planet seen with comet-seeker. Thin clouds. No stars seen near the sun. Corona very brilliant. Several drawings secured and photographs taken. "D. P. TODD"

It is telegraphed to the *Tribune* from—

"*Havana*, July 30.—Yesterday the total eclipse of the sun was visible in this latitude. The sky was perfectly clear, and complete observations were made. A report of the results obtained was expected to-day, but the scientific commission which took observations at Mariel, where the meridian passes, has not returned yet."

"*Quebec*, July 30.—The eclipse of the sun yesterday was witnessed under the most favourable circumstances."

"*Washington*, July 30.—The Signal Service Observer at Virginia City, Mont., reports to the Chief Signal Officer as follows:—'Our four telescopic stations have got all the contacts nicely, and three sketches of the corona.'"

OUR ASTRONOMICAL COLUMN

THE SATURNIAN SATELLITE HYPERION.—The following ephemeris of Hyperion is deduced from the elements which were calculated by Prof. Asaph Hall, upon his observations in 1875 with the Washington 26-inch refractor.

AT GREENWICH MIDNIGHT.

The plane of the orbit of the satellite is assumed to coincide with that of the ring, and as the earth has passed through the plane since the period included by the ephemerides which appeared in this column last year, the apparent motion of the satellite is now reversed, or the angles of position diminish. The above ephemeris includes an entire revolution of the satellite, and will serve, if necessary, to afford an idea of its position at any time during the present opposition, remarking that the satellite will be at its peri-saturnium at the following times: August 15·0939, September 5·4052, September 26·7165, October 18·0278, and November 8·3391.

OLBERS' STAR NEAR γ PEGASI.—On September 27, 1820, Olbers remarked a star of 6·7 m. not entered upon Harding's map, and which Harding had not seen during two comparisons of it with the heavens. It was somewhat brighter than 39 and nearly equal to 40 Piscium. Olbers accounted for it not having been observed on the meridian by the fact of its culminating within a few seconds of γ Pegasi. He watched it during the remainder of the season without noticing any change in brightness, and it was from the circumstance of his attention being thus directed to this quarter of the sky that he made an independent discovery of the comet of 1821. The star is in the *Durchmusterung* as 7·5 m., and was observed once by Argelander (October 24, 1861), the resulting position for 1855·0 being R.A. 0h. 5m. 41·8s., N.P.D. 73° 52′ 56″. Bessel did not observe it, but it is suspicious that he has a star 9m. only, preceding Argelander's position of Olbers' star 7·0s. and 3′ 58″ to the north, where the *Durchmusterung* has no star. It is a case for some one of those observers who are occupied with the variable stars to explain.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

A New Mineral

MR. BARNETT, of Chyandour, near Penzance, sent to the British Museum some time ago a mineral which appears to be new.

It is white with a slight tint of blue or greenish blue, and occurs as a layer sometimes of a quarter of an inch thickness, generally of a uniform fibrous structure, lining hollows or encasing quartz and other minerals. It is associated with earthy chlorite and quartz; iron pyrites, some copper pyrites, and mispickel being disseminated in the lode-material. Scorodite in boss-like aggregations also occurs with it, and in at least one instance the interior of the bosses of scorodite is filled with the mineral in question.

Dr. Flight has analysed it, and, though the mode in which the water is present has to be established more certainly, the general result of the analysis may be stated to be the assigning to the mineral a formula expressed, in "old style," as

$$3R_2O_3, As_2O_5 + 16H_2O,$$

R_2O_3 representing alumina with a notable amount of ferric oxide. The tint seems due to about one per cent. of copper, and a small amount of a sulphate is also present. The presence of the sulphate and general character of the composition would lead one to place the mineral with Pitticite, or "iron-sinter." But the formula, as Dr. Flight has pointed out, is so nearly that of an arsenical (instead of a phosphatic) Evansite that the true place of the mineral seems to be near the Evansite of David Forbes. I propose to call it Liskeardite, and to describe it more precisely hereafter. N. S. MASKELYNE

British Museum, Mineral Department, August 12

The Colouring of Birds' Eggs

WITHIN the last few months several notices have appeared in both England and Germany of supposed newly-discovered

colouring matters in the shells of birds' eggs. Permit me to call attention, through your journal, to a long and detailed paper on this subject published by me, about four years ago, in the *Proceedings* of the Zoological Society of London. Apparently the authors who have lately treated on this subject have not been aware of the existence of this paper. As far as they go, the facts they have described fully confirm my conclusions; but, as I have shown, different birds' eggs contain at least five perfectly distinct coloured substances, and not, as Liebermann says, only two. One of these is closely related to a product of the decomposition of hæmoglobin and another to the bile pigments, it and the bile of birds yielding the same well-marked product on oxidisation. H. C. SORBY

Kingstown, Dublin, August 6

The Limbs

IN his interesting papers on "The Genesis of the Limbs," which have recently appeared in NATURE, Mr. Mivart mentions that I have represented the limbs as modified portions of a primitively continuous inferior azygos fin.

That view was stated by me at length in a paper in the *Journal of Anatomy and Physiology*, 1871, vol. v., p. 59. It was formed from the following considerations among others—First, that the mesial, or azygos fins, are essentially double organs, being formed from the coalesced elements of the dorsal and ventral plates of the two sides, and being furnished with muscles, nerves, and blood-vessels, from the two sides. They may therefore be the representatives of organs which remain double, that is, of organs in which the lateral elements do not coalesce. Secondly, the limbs and the azygos fins do not co-exist in the same region. The limbs are formed where the ventral plates are kept apart and expanded by the presence of the visceral cavity, so that the elements which in the dorsal and postanal regions meet and unite into azygos fins, are here separated and grow out as lateral limbs. The ventral plates are, moreover, continued onwards beyond the outgrowing line of the limbs, and form the median portion of the visceral wall which lies beneath and between the limbs on the two sides. Thirdly, there is such a marked resemblance between the ventral fins in some fishes and the anal fins, that the transition from the one to the other is easy; the dagger-shaped pelvic bones being the representatives of two or more coalesced intraspinous bones and the ray bones of the one set being, in like manner, the representatives of the ray bones of the other.

Mr. Balfour in his admirable papers on "The Development of Elasmobranch Fishes," in the *Journal of Anatomy and Physiology* shows (vol. xi. p. 133), that the limbs are the remnants of continuous lateral fins, and that the ridges from which they are developed are in every way like the folds from which the unpaired fins are formed, but the development and growth are confined to two special points on each side instead of being continued, as in the case of the dorsal and anal fins, along a greater length of the fold. He further remarks that, externally, they closely resemble the unpaired fins, and both their position and nervous supply indicate that they do not belong to one special segment of the body. The lateral ridges, from which they are developed, I conceive to be the continuations of the diverging lateral halves of the essentially double ridge of the caudal fin kept asunder by the presence of the visceral cavity. These are but little separated in the position of the ventral fins, and are more so in the position of the pectoral fins. If this be so, the limbs are specialised differentiations of primitively continuous lateral folds—of portions, that is, of the diverging plates of the median fold from which the caudal fin is developed.

I cannot, however, assent to Mr. Mivart's view that the limbs are mere appendages to the axial system, or admit that either they or the limb girdles are the result of centripetal growth, "due to the in growth of originally superficial structures—exoskeletal hardenings which have grown inwards and become endoskeletal." The limb girdles are found in the same plane of the mesoblast as the ribs, and are, as I have shown in the "Anatomy of the Cryptobranch" (*Journal of Anatomy*, vol. vi. p. 9, and *Observations on Myology*), though not necessarily the serial homologues of the ribs, yet like them the result of ossification in the ventral transverse intermuscular septa. As they grow out they carry before them envelopes not only of skin, but of muscle, derived from the body-wall, which become differentiated according to the requirements. Moreover, although the ridges from which they are primarily developed may appear at first as epiblastic projections, these are soon supplemented by accumulations of mesoblastic tissue in which the components of the limbs are chiefly formed. G. M. HUMPHRY

Cambridge, August 1

The Darkness of Caverns

THE impenetrable darkness of caverns has been for a very long time a recognised fact, without its cause having been satisfactorily explained. This darkness vanishes but partially before torch-light, and that only in a very limited radius. I, in my explorations in the caverns of Spain, had also noticed this circumstance, and now that I have verified it in others in Switzerland, I venture to think that I have found the explanation of this phenomenon.

The walls as well as the roof and floor of caverns are continually covered with moisture, which works without interruption in condensing the corpuscles that float in that circumscribed space. It thus performs the same function that the glycerine does which varnishes the sides of the crystal box by means of which Prof. Tyndall obtains an optical vacuum, the light diffusing itself imperfectly from want of those atoms which act as reflecting bodies. I have had occasion to verify my supposition by scattering around the torch very fine dust of different substances. The brightness diffused itself regularly all the time that the dust maintained itself in the required state of closeness and fluctuation, and vanished again slowly as the dust spread or deposited itself. The earth or common dust is the one which, in my experience, has produced the best effect.

SALVADOR CALDERON

Scent and Colour in Flowers

THE extension of our perceptive faculties of sight and hearing by various optical and acoustical instruments may enable us to comprehend the possibility of these faculties existing in other creatures to a degree so far surpassing ours as to seem a difference almost of kind. So the sight of the vulture would seem to be paralleled by the faculty of smell in moths, as evidenced by the detection of distant females by males. It would seem probable that the sense of smell may guide insects at a far greater distance than that of vision; for a consideration of the structure of the eyes of insects leads to the belief that they are not capable of forming clear images of distant objects. While, then, the scent of its blossoms may attract insects to a plant, their colour will act as a subsequent guide to the individual flowers, just as variegations undoubtedly act as honey-guides when the insect reaches the flower. This view is borne out, firstly, by the undoubted connection between perfume and pollination, shown by Morren in the case of the orchid *Maxillaria*, whose aromatic perfume lasts till pollination; and, secondly, by the well known connection of odour both with colour and with natural groups, white flowers being mostly sweet-scented, brown and orange ones most fetid. The insect could thus identify species before seeing them. Mr. Wallace has been, perhaps justly, blamed by a writer in the *Gardener's Chronicle* for saying that brightly-coloured flowers are seldom scented, and Dr. Taylor by "J. S. G." (NATURE, vol. xviii. p. 277), for saying that white flowers open mostly at night. It would, I think, be truer to say that few flowers are both variegated and scented, *i.e.*, that scented flowers are mostly monochromous, and that the majority of night-blowing flowers are white. The latter is a very different matter from saying that the majority of white flowers are night-blowing. We can perceive with difficulty that one part of a flower is more scented than another, yet scent may replace the dots and point-indicating lines of variegation to the senses of an insect. Nature not only often effects one purpose by divers means, but also uses one means for divers ends; so just as colour exists in plants, not only to attract insects, we can understand it being absent in some white flowers simply as a phenomenon of degradation and not as one of specialisation. The dog-rose, white convolvulus, and daisy, mentioned by Mr. Gardner as closing at eventide, are all scentless. The first, according to Dr. Hermann Müller, is visited by six hymenoptera, two diptera, and twelve coleoptera. The convolvulus does not close till between eight and ten P.M., and re-opens by moonlight. It is visited by two diptera, *Podura*, *Thrips*, one coleopteron, two hymenoptera, and the *Sphinx con-*

volvuli, L. This is a dusk-loving hawk-moth, which also visits the honeysuckle. The daisy is visited by nine hymenoptera, thirteen diptera, three coleoptera, and two lepidoptera, viz., the least meadow brown and the common blue butterflies. Many flowers, like *Lychnis vespertina*, remain open without exhaling their perfume, and I think Mr. Gardner will find that most of the subduedly-coloured flowers which are open at night give off most perfume, and are visited and fertilised by moths rather at dusk than in the dark, whilst the white ones remain fragrant still later. The clearly-cut discs of white of *Lychnis vespertina* are the last objects our eyes can often discern on a midsummer night's ramble. Of course variegation on the moths themselves would be as useless, from the point of view of sexual selection, as on the flowers from that of insect-fertilisation. Though it is to a certain extent true that like causes produce like effects, in investigations into phenomena so complex in their etiology as those of biology we must, I think, be more mindful that the converse that like effects are the result of like causes by no means necessarily follows. G. S. BOULGER

11, Burlington Road, Westbourne Park, W.

SCIENTIFIC SERIALS

Rendiconto delle Sessioni dell' Accademia delle Scienze dell' Istituto di Bologna.—The more important papers read at the Academy during the academical year 1877-8 were the following:—On the metamorphosis of plants, by Prof. G. B. Ercolani. The author specially refers to the transformation of a cryptogamous plant of the genus *Uromyces* into a phanerogamous dicotyledon, *Cuscuta europæa* L., and the return to the primitive cryptogamous form apparent in the seeds and branches of the *Cuscuta*.—On the velocity of light in transparent magnetised bodies, by Prof. A. Righi.—On the concentration of a magnetic solution near the pole of a magnet, by the same.—On the curves with equal normal principals, by Prof. A. Fais.—On some researches to ascertain whether from cadaverous matter, from albumen, or yolk of egg, volatile phosphoretted products are evolved, and on an excellent means of discovering free phosphorus in minute quantities, by Prof. Francesco Selmi.—Crystallographical researches, by Prof. Carlo Maragoni. The author describes some theoretical and experimental researches, and their application to the natural history of crystallised minerals.—Contributions to the flora of the Bolognese province, by Prof. Girolamo Cocconi.—Researches on the varying nature of the caloric emitted by various bodies heated to 100° C., by Prof. E. Villari.—On four species of noxious insects, inhabiting pines and birches, by G. Bertoloni.—On the calcareo-siliceous conglomerates of Sasso Cardo and of the Rio Fonti, and on the origin of pyrites, by Prof. Domenico Santagata.—Critical observations regarding some recent Italian crystallographical publications, by Prof. Luigi Bombicci.—On comparative psychogeny and the attempts to establish a zoopsychological classification, by Prof. Siciliani.—Note on a theorem in the theory of binary forms, by Prof. Francesco d'Arcais.—Observations regarding the existence of rudiments of upper canine teeth and incisors in the embryos of oxen and sheep, by Dr. G. P. Piana.—Anatomy and physiology of *Surilla Neapolitana*, by Prof. Salvatore Trinchese.—On a problem in undetermined analysis occurring in the geometrical theory of the transformation of plane figures, by Prof. F. P. Ruffini.—Geometrical studies on the molecular equilibrium, by S. Canevazzi.—On some gigantic bird-remains, probably belonging to *Aepyornis* or *Ruck*, by Prof. G. Bianconi.—On the internal texture of the eye of *Sphinx*, by Prof. G. V. Ciaccio.—On the origin and structure of the humor vitreous, particularly in the embryos of the two first classes of vertebrates, by the same.—On the whale of Taranto and the *Macleayius* of the Paris Museum, by Prof. G. Cappellini.—On the emery from S. Lucca and Paderno, and its fossils, by Dr. Lodovico Foresti.—On the reticular structure of the red corpuscles in the blood of *Torpedo*, and of the nerve substance of frogs, by Prof. Salvatore Trinchese.—Researches on the central nervous system of *Squilla Mentis*, by Dr. G. Bellonci.—Results of experiments made at the Royal Botanical Gardens of Bologna upon some species of *Eucalyptus*, and upon a new grass recently introduced in Italy, by A. Bertoloni.—On the nerve ends in the skin of bat's wings, by Dr. Agostino Rossi.—On the formation of protoxide of iron in the metallic state in the wet way, by Prof. Francesco Selmi.

SOCIETIES AND ACADEMIES

MANCHESTER

Literary and Philosophical Society, April 2.—E. W. Binney, F.R.S., F.G.S., president, in the chair.—On aurin, by R. S. Dale, B.A., and C. Schorlemmer, F.R.S.—The origin of some ores of copper. Part II., by Charles A. Burghardt, Ph.D.

April 16.—Note on the occurrence of dioptase on Chrysocolla, from Peru, by Charles A. Burghardt, Ph.D.—On the internal cohesion of liquids and the suspension of a column of mercury to a height more than double that of the barometer, by Prof. Osborne Reynolds, F.R.S. The object of this communication is in the first place to show that certain facts already fully established afford grounds for believing that almost all liquids, and particularly mercury and water, are capable of offering resistance to rupture commensurate with the resistance offered by solid materials; in the second place to describe certain experimental results which, as far as they go, completely verify these conclusions and subvert the general ideas previously mentioned as to the limits to the height to which mercury can be ssupended in a tube or water raised by suction; and, in conclusion to explain the nature of the circumstances which have resulted in the practical limits to these phenomena.—On the estimation of hyposulphites and sulphites, by J. Grossmann, Ph.D.—Note on the action of iodine trichloride upon carbon bisulphide, by J. B. Hannay, F.R.S.E., F.C.S.

PARIS

Academy of Sciences, August 5.—M. Peligot in the chair.—Probable new observation of the planet Vulcan by Prof. Watson, by M. E. Mouchez.—On the orbito-ocular phenomena produced in mammals by excitement of the central end of the sciatic nerve, after excision of the superior cervical ganglion and the superior thoracic ganglion, by M. A. Vulpian.—New note on the progress of phylloxera in the two departments of Charente, in connection with the last communication of M. de la Vergne, by M. Bouillaud.—Rate of propagation of excitations in the motor nerves of the red muscles, abstracted from the power of the will, by M. A. Chauveau.—On the fundamental covariants of a cubo-quadratic binary system, by Prof. Sylvester.—On the baking of plaster, and on the manufacture of plasters by slow coagulation, by M. Ed. Landrin.—No mycelium intervenes in the formation and in the normal destruction of swellings developed under the influence of phylloxera, by M. Maxime Cornu.—On the abnormal solubility of certain bodies in soaps and alcaline resinates, by M. Ach. Livache.—On the vibratory forms of solid bodies and of liquids, by M. C. Decharme.—Note on the intra-Mercurial planet, by M. Gaillot.—Results of solar observations during the second quarter of 1878, by M. Tacchini.—Action of chloride of zinc on methylic alcohol; hexamethylbenzine, by MM. Le Bel and Greene.—Researches on the connections which exist between the weight of various bones of the Biscayan whale (*Balæna biscayensis*), by M. S. de Luca.—On *Prosopistoma punctifrons*, Latr., by MM. E. Joly and A. Vayssière.—On the influence of atmospheric electricity on vegetation, by M. L. Grandeau.—Age of the Mont-Dol bed; constitution and formation of the low plain called Marais de Dol, by M. Sirodot.

BRITISH BARROWS

British Barrows. A Record of the Examination of Sepulchral Mounds in various Parts of England. By William Greenwell, M.A., F.S.A. Together with *Description of Figures of Skulls, General Remarks, Pre-historic Crania, and an Appendix.* By George Rolleston, M.D., F.R.S. (Oxford: Clarendon Press, 1877.)

THE pre-historic inhabitants of Europe are now exciting an interest in the minds of thoughtful men which, twenty years ago, would have seemed impossible, and which can no longer be ignored by the historian. The story of man in Great Britain is rapidly being unfolded, principally by the careful and scientific exploration of the various remains which are eloquent of the condition of things that passed away before the art of letters was known in the north; and, among those who have been mainly instrumental in bringing this about, Mr. Greenwell will ever deserve a foremost place. He has devoted years of patient labour to the accumulation of facts; and in the present work he records the results of the examination of upwards of 230 burial mounds, the greater number being in the wolds of eastern Yorkshire. He has also had the advantage of the aid of Prof. Rolleston, by whom the human remains—fortunately now safe from dispersal, in the Oxford Museum—have been classified and described, in the latter part of the book.

The general results of the exploration are thrown into an introduction of 130 pages, carefully written, and highly suggestive of new lines of thought. The barrows vary in size and shape very much as the graves and tombs in our own graveyards, where the rich man's memory is preserved by the large mausoleum, while the poor man's resting-place is marked merely by the little mound of earth, soon to be lost in the general surface. Those in the Yorkshire wolds are either circular or "long," the former being the more abundant, and are frequently surrounded by a ramp or a ditch. In some cases this was within the base of the barrow, and very generally it was incomplete. "This very remarkable feature," writes Mr. Greenwell, "in connection with the inclosing circles, is also found to occur in the case of other remains which belong to the same period and people as the barrow. The sculptured markings engraved upon rocks, and also upon stones forming the covers of urns or cists, consist in the main of two types—cup-shaped hollows, and circles, more or less in number, surrounding in most cases a central cup In almost every instance the circle is imperfect, its continuity being sometimes broken by a duct leading out from the central cup; at other times by the hollowed line of the circle stopping short when about to join at each end. The connection of the sculptured stones, if so they may be termed, with places of sepulture brings them at once into close relationship with the inclosing circles of barrows, and it is scarcely possible to imagine but that the same idea, whatever that may have been, is signified by the incomplete circle in both cases. The rings of gold and bronze, of various shapes, some of which in their construction show that the penannular form is not caused by the requirements of their use, appear to represent the same incomplete circle. In fact, if some of the gold rings were figured upon stone, they would appear in the very similitude of the circular rock sculptures." Our author suggests that it may have been intended to prevent the exit of the spirits of those buried, though in that case it is hard to see why the spirit should not have found its way out through the opening. It seems more probable that if the barrow represented the hut inhabited by the living that the circle round it would represent the trench, or the inclosure of the hut, and that this would necessarily be incomplete, to allow of access to the habitation.

The dead were buried in the barrows of the wolds very generally in the condition and clothing in which they died, the proportion of cases of inhumation to those of cremation being as 301 to 378, or about 80 per cent. In all probability both customs were carried on simultaneously, as was the case in ancient Rome, where, however, inhumation was mainly confined to the lower classes. Where inhumation had been practised the body was buried in the crouching posture in which life had departed, and which would be natural where the sleeping place was not well protected against the cold, and the covering was scanty. This interpretation, due to the ingenuity of Mr. Evans, is most likely true.

The burnt and broken bones of various animals used for food in the barrows are probably the remains of funeral feasts held at the time of the interment, or from time to time afterwards, or they may be the remains of food offered to the dead. Splinters and various manufactured implements of flint, and fragments of pottery, also occur sometimes in great abundance, and probably symbolise some religious idea. Fragments of flint were used in interments at least as late as the fourth and fifth centuries after Christ in this country; for they were found in considerable quantities inside the oaken coffins in the Romano-British cemetery, referable to the above date, explored at Hardham, Sussex, in 1866.

Where cremation was practised the funeral pile was sometimes kindled upon the spot, which was afterwards occupied by the barrow, but at other times the ashes of the dead were collected and deposited somewhere else. In several barrows curious perforated vessels of pottery, or "incense cups," were met with, which may have been used to convey the sacred fire to the pile. The ashes of the dead were placed in urns sometimes highly ornamented, and those things which delighted the dead most or were most useful to him, were deposited in the tomb. Flint scrapers, flakes, arrow-heads, beads, hammer-axes, celts, domestic pottery, and a few bronze articles. The number of objects buried in each barrow varied according to the wealth of the dead and the estimation in which he was held by the survivors.

The animal remains in these barrows prove that the ancient inhabitants of the Wolds were no rude savages living mainly on the chase. They possessed flocks and herds, consisting of well-known domestic breeds—the small Celtic shorthorn, now represented by the mountain cattle of Wales and Scotland, the pig, the horned sheep or goat, the horse and the dog, the two last being

the rarest. They also ate venison of the stag (*Cervus elaphus*). Their place in the archæological scale of culture is fixed by the few and simple forms of bronze articles in the barrows, the simple wedge-shaped axe, and the short broad dagger, in association with various articles of stone, coupled with the absence of the higher bronze types, such as the sword. They belong to the early bronze age. The absence of the sword is also noticed in the tumuli of France, referred by Mr. Chantre to the same horizon. At this time the knowledge of bronze was gradually finding its way northwards from the Mediterranean centres, and the simpler forms preceded the more complex and elaborate.

Nor are we left in doubt as to the ethnical relations of these ancient Yorkshiremen. Prof. Rolleston's elaborate examination of the crania and skeletons reveals the fact that the two types—the small long-headed or "Iberian," and the tall robust round heads, or "Celtic," which have been traced by Thurman, Huxley, Busk, and myself, from Scotland to the Mediterranean, and from the Rhine to the Pillars of Hercules, occur in the round barrows side by side in intimate association. The former of these, "the Silurian" of Prof. Rolleston, is considered in this work as the older of the two. According to Dr. Thurman it was dormant in Britain in the Neolithic age, at the close of which it was invaded by "the Celtic" or "the Cimbric" of Prof. Rolleston. The truth of this view is confirmed by the fact that the dead of these two races rest peacefully together in the round barrows of the wolds referable to the early bronze age. In concluding this review it remains merely to say that this valuable work fills a void in the archæological record of Great Britain, and that it contains a larger mass of accurately observed facts than any book hitherto published relating to the Bronze Age in this country.

W. BOYD DAWKINS

THE ECLIPSE OF THE SUN

THE following letter appears in the *Daily News* of Tuesday, from its Special Correspondent, dated Manitou, Foot of Pike's Peak, Colorado, August 2:—

Since the eclipse I have had no easy time of it. To gain accurate information concerning the work done along the long north and south line, on which, as your readers already know, the stations were located, it was necessary to return over the crest of the Rocky Mountains at Sherman (8,200 feet) down to Cheyenne, and then go as far south, by the Colorado Central line, as Colorado springs, passing Denver on the way. Manitou, whence this letter is written, is about six miles from the latter place on the old and famous Ute trail, a road much improved in these later days for the needs of the enormous traffic connected with the mines at Leadville. The place itself is lovely—so lovely, indeed, that although it is over 2,000 miles from the eastern seaboard, the hotels and baths (iron and alkaline) formed but a nucleus for a large encampment, tents dotting the slopes in all directions. The newly-published geological map of this region with which Prof. Hayden, with his wonted generosity and forethought, had supplied some of the astronomers, enabled them to revel with more or less success in the wonders of the famous "Garden of the Gods," and Glen Eyrie, where the rocks put on everything they can in the way of uncommon arrangement and colour. Vertical beds of limestone and sandstone 300 feet high, and not many yards thick, even at the base—each spire excelling the other in some glorious colour, including all those we see in an English sunset—is a sight never to be forgotten, even if Pike's Peak, with its patches of snow, were not seen through such gigantic and weird portals.

Here, then, we met the Pike's Peak and the Las Animas parties, all rejoicing over their success. Two of the former—General Myer, the creator and chief of the wonderful meteorological signal surface, and Prof. Cleveland Abbe—have suffered somewhat from their sudden transference from the plains to a height of above 14,000 feet. The latter, indeed, had to be transferred on a litter, by the General's order, to a station at mid-height before the eclipse. But the journey to Manitou does not exhaust my wanderings. Much was expected from Prof. Holden's party at Central City, easily reached from Golden City by one of the most wonderful railways in the world. To Central City, therefore, I went up to a point called Black Hawk. The railroad is filched from the bed of a stream at the bottom of a true cañon. Here rail and river together are not fifteen yards broad, and precipitous cliffs 1,000 feet high shut out the light. Here, again, the cliffs recede, the river bed widens, and miners—American and Chinese—are engaged in extracting the precious gold from the turbid water and its bed, some of the miners making in this way 1,500 dollars a week. From Black Hawk to Central City there is no possible approach except up the side of a steep hill. The railway accepts the condition, and zigzags up—now engine, now cars, foremost—till the nest of stamping mills and smelting furnaces at Black Hawk looks like a speck below.

The party at Central City had been as fortunate as the rest in the matter of weather, and their station, on the top of Teller's Hotel, in the middle of this strange mountain community, had proved a very convenient one. After my last letter to you, I became acquainted with the fact that Mr. Burnham, so well known for his work on double stars, and whose eye seems to be keen as was formerly Dawes's among us, was going to observe the eclipse on behalf of the *Chicago Times*—a piece of newspaper enterprise worthy of imitation. I tried to find him when I passed through Denver to Prof. Young's camp, but was unsuccessful, though I was fortunate enough to see Prof. Young himself, whose party was second to none either in *personnel* or in their means at the disposal for securing good results.

My telegram to you, immediately after the eclipse, was necessarily based upon the most meagre materials, and laid emphasis upon those parts of the combined attack which were most strongly represented at the northern stations. Still, now that the complete information is before me, I have very little to alter, so singularly and exceptionally do the observations support each other in the main; and I say in the main, because on some points there is enough disaccord to make the astronomers already look forward to the next eclipse. Without going too much into detail I will go over the ground in the light obtained by personal communication with the chiefs of the different parties, with the single exception of Prof. Hall, who is a most skilful and competent observer, and to whose opinion, as the discoverer of the satellites of Mars, the greatest weight is to be attached. The corona was much less brilliant than usual. Those who have observed the greatest number of eclipses are strongest on this point. The contrast, perhaps, is most striking between this eclipse and that of 1871 observed in India. Now that this fact is recognised, the naturalness of it is apparent to everybody. We know that the sun's activity and the various meteorological and magnetical conditions on our own earth which depend upon or are connected with it wax and wane every eleven years or so. This is termed the sun-spot period. Thus the sun was very active in 1871, and it will be again very active in 1882. It is very sluggish now, and it will be sluggish again in 1889. In 1871 we had many spots, many prominences, many mag-

netic storms and auroræ, heavy rainfall, and, let me add, no famines to speak of. Associated with these we had a large corona. This year there are no spots, the prominences are rare, the magnets were never so quiet, there are no auroræ, and we are passing through a famine period. Associated with these we had a small corona. Hence it is that the astronomers agree that this year another connecting link has been added to the chain which binds together the solar changes.

On another point mentioned in my telegram the evidence is overwhelming. Since the use of the spectroscope in this branch of inquiry the spectrum of the corona has been observed to be a mixed one—that is, bright lines as well as a continuous spectrum have been traced in it. In 1869 and 1871 these lines were very bright to the eye—much brighter than the continuous spectrum, while in 1875, when the spectrum was photographed for the first time, the record showed the lines to be much brighter than the continous spectrum. Now, as it generally happens that when in our laboratories we study gaseous spectra there is a faint continuous spectrum accompanying the lines, it was thought that the spectrum of the solar corona might have a gaseous origin exclusively. This year's observations have quite dispelled this idea, for the two elements of the corona spectrum, to which attention has been drawn, instead of varying directly, vary inversely. The continuous spectrum has been seen and photographed by itself, without any bright lines. Now for the interpretation of this hieroglyphic language. The gases which were high up in the sun's atmosphere at the last epoch of maximum sun-spots (1871), have almost entirely retreated to a lower level; as these gases are to a large extent carriers of heat from the interior to the exterior of the sun, the exterior is cooler in their absence, and indeed cool enough to allow it to hold in suspension a larger percentage of solid and liquid particles to which the continuous spectrum is due. A natural suggestion touching these particles is that they consist of meteoritic matter, and all the phenomena to which attention has been drawn can be explained by supposing that these meteorites surround the sun, and that at the minimum sun-spot period they can exist lower down in consequence of the reduced temperature of the sun's atmosphere at that time. If this suggestion, which is the one in favour out here, be endorsed we have a partial cause of reduced solar radiation at that time. I cannot quit this part of the subject without referring to the wealth of astronomical resources which have been brought to bear upon it. Paper astronomers have been now for a long time, I doubt not, very lucratively employed in proving that it was impossible to do exactly what has been done. Dr. Draper, who ranks deservedly high among solar observers, bears off the palm by the strength of his attack. He used a camera of six inches aperture and of only twenty-one inches focal length, and, by means of a Rutherfurd grating two inches square, obtained a photograph of the corona and two of its spectra with the same instrument. The plates were exposed during the whole of totality, and it is encouraging for future work to know that much less exposure would have sufficed to secure the precious records, although the continuous spectrum recorded is the most difficult to obtain. Prof. Harkness used an instrument of nearly equal power, though of slightly different arrangement. The smallest instruments employed—ordinary portrait cameras with a grating in front—also gave the same result, though, of course, on a much smaller scale.

Next comes the endorsement of the fact that the coronal light is due partly to solar light—that all the light it sends to us is not its own. Prof. Barker, with Dr. Draper's party at Rawlings, though he saw no bright lines, saw dark ones in abundance; and Prof. Morton got distinct traces of radial polarisation, thereby endorsing the result obtained in 1871. The object of these observations by the polariscope is to determine whether and in what plane light is reflected; and for the light to be reflected to us by particles in the sun's atmosphere we must imagine our eye, the centre of the sun, and the particle to lie in one plane. If, further, we imagine an infinite series of particles surrounding the sun, we shall have an infinite series of these planes, and each radius of the sun will lie in one of them. I have been particular in stating this, because Prof. Hastings, a great authority in optical matters, declares that the reflection takes place at right angles to these radial planes; in other words, he declares that the polarisation is tangential and not radial. As has been well remarked, this result is easily explained by supposing ice crystals to be present in the sun's atmosphere, and no other solution lies on the surface. I believe no one is more astonished than Prof. Hastings at his observation; and here again we see the necessity of relaxing no efforts and letting slip no opportunity of garnering the observations with which eclipses alone supply us.

Finally, as to the construction of the corona. Numberless records of this, both visual and photographic, have been secured, and as usual, though there is almost perfect agreement as to the structure of the lower portion, the rays and streamers have been very variously observed. The upper and lower portions of the sun were graced by the most exquisite tracery, bending over right and left like plumes of ostrich feathers, the intervals between them being of a delicate blue. Near the solar equator the structure was not so obvious. Still, it was there, for Prof. Bass saw it come out *and pulsate* after he had fixed his eye on one portion for two minutes. The structure was distinctly less filamentous than in 1871. With regard to the streamers there appears to have been two sets—one along the ecliptic, giving rise to the appearance of a wind vane seen by one set of observers; another, at right angles to this, seen by another set. Neither of these systems of streamers was visible in a telescope, though the base of the ecliptical ones appears on the photographs. On this point the greatest weight must be given to the observers on Pike's Peak, 14,147 feet high. Most fortunately the weather there as elsewhere was superb, and the corona was seen as it was never seen before. The clearness of the sky in this region when the weather is good is simply wonderful. The Milky Way seems to have deep holes in it, and the individual stars shine out. Even at Rawlings Prof. Watson could see the satellites of Jupiter with the naked eye. At Pike's Peak General Myer saw the corona for fully five minutes after totality was over, while in India, in 1871, the much brighter corona was seen at sea-level for only three minutes after the eclipse was over. Prof. Cleveland Abbe, who, as already stated, observed below the Peak, saw the ecliptic streamers extending to a distance of twelve solar diameters, while he saw nothing of the north and south ones, pretty conclusive evidence in favour of their subjectivity, and from their appearance he has little doubt of their being meteor streams. Prof. Newcomb saw the ecliptic streamers almost equally well at Separation by the help of a novel contrivance. He had a disc erected on a high pole at some distance from his telescope so that he could momentarily cover the dark moon and corona and observe the external phenomena with the naked eye. In this way he saw the streamers extending nearly as far as Prof. Abbe did. Still he explains them differently. He considers that they indicate the true zodiacal light. No doubt there are difficulties surrounding both suggestions, and here again we see the need for future thought and work. The regions in which the various parties were located enabled many of the connected phenomena to be observed as they had never been before. From Pike's Peak, with its horizon of 150 miles on all sides, the shadow of the moon sweeping rapidly through the air was a very tangible thing and seemed to

be solid enough to sweep all before it. It was noticed on the air and on the very buttresses of the Peak that the boundary of the shadow was strongly coloured in the prismatic order. The wide extent of Alcali Plains round Separation and Preston—plains broken by nothing save the wonderful avenue of telegraph poles along the railway, and the solitary water tank and telegraph operator's house, enabled these and the associated phenomena to be seen well there also, and there were just sufficient clouds above the eastern horizon to bring out into strong relief the retreat of the shadow through the air, while during the eclipse the leaden light on the desolate plains gave rise to an intense feeling of loneliness and weirdness. The daring genius of Edison has left its mark on this eclipse. So soon as he had completed his tasimeter he saw its applicability to eclipse work in determining the presence of heat waves in the radiation from the corona. I had the rare privilege of seeing the great inventor at work gradually increasing the sensitiveness of his wonderful instrument with the most consummate knowledge of principles and contempt for elaboration, until at length during the eclipse he was rewarded by seeing the speck of light on the attached Thomson galvanometer give a decided swing from its zero on the dark moon when the image of the corona was brought on the fine slit in the plate which shielded the tasimeter from its surroundings. The instrument was too new to succeed in other hands, even those of Prof. Young; but he was not to be beaten. Driven from one instrument he took up another—the thermo-electric pile—and was rewarded by finding a heat line in the ultra-red. This opens out another new line of work in future eclipses; and so science advances. Rumour here says that one distinguished astronomer remained away because he considered eclipses "played out." What a lesson he has learned ere this touching the need of that receptivity to which I referred in my former letter!

Mindful of your space I must here conclude my statement of the more salient solar phenomena observed, the detailed discussion of which will occupy the astronomical world for some time to come. I shall have been very unfortunate and unworthy of my post if I have not succeeded in convincing your readers that several important advances have been made, and that the work done on the eclipse of 1878 will rank high in astronomical records. I have not yet, however, quite finished the story I have to tell. Students of solar physics may congratulate themselves that the gravitational astronomers will in the future insist upon having their finger in the eclipse pie. In my telegram I was enabled to announce the position of the body observed by Prof. Watson near the sun. Since the telegram was dispatched the matter has been seriously discussed by Prof. Holden and others, and little doubt remains that a new major planet has been discovered, if, indeed, Vulcan has not been refound. Prof. Watson's work has been acknowledged on all hands to be a veritable *tour de force*. The Naval Observatory instructions contained a map of all stars near the sun down to the seventh magnitude. Prof. Watson determined to review all these, and provided his equatorial with paper circles on which to mark the difference of right ascension and declination between any body not marked on the chart and the sun. After the eclipse, and before the instrument was dismounted, Prof. Newcomb and Mr. Lockyer saw the precious record *in situ*. It was here at Manitou that Prof. Watson again reviewed his work, and despatched a telegram to the Smithsonian Institution corroborating the one I had previously sent to you.

The English observers are full of appreciation of the reception they have met with from their American *confrères*. Prof. Thorpe and Dr. Schuster were the guests of Prof. Hall's party at Las Animas. Mr. Lockyer, invited by General Myer to Pike's Peak, by Dr. Draper to Rawlings, Prof. Newcomb to Separation, and Prof. Wright to Las Animas, decided for Rawlings, where Dr. Draper placed all the resources of his observatory at his disposal. A thing unknown in England—that is, a travelling railway photographic car—being, however, placed at the disposal of the astronomers by its proprietor, Mr. Silvis, it was decided at the last moment to establish another station, and on the morning of the eclipse Prof. Watson and Mr. Lockyer proceeded to Separation, a station on the Union Pacific Railway, between the eclipse camps there and at Preston.

The *Times* correspondent, writing from Pueblo, South Colorado, July 31, states that Dr. Schuster brought out with him a couple of fluorescent eye-pieces, with a view of re-determining the position of the lines he observed in 1875; but a too-confiding faith in the tender mercies of the baggage-men in charge of the instruments led to the utter destruction of one of the eye-pieces, while the other was so injured that it was impossible to get it into order in time for the eclipse. Indeed, nearly all the instruments, in spite of most careful packing, suffered more or less damage, either during their canter—for such it can only be called—along the Western railroads, or at the hands of the "baggage-smashers" who took charge of them at the depôts. The baggage arrangements of American railroads are doubtless perfect in theory; but the practical application of them is simply ruinous to scientific apparatus.

The newspapers are filled with allusions to the phenomenon; its effect on animals, on the colours of objects, and on their visibility, was noted everywhere. The darkness was far from being so great as was anticipated; the decrease of temperature was, however, very considerable. At La Junta it fell from 96° to 80°; at the time of last contact it had again risen to 93°. In Pueblo the fall was as great as 23½°—*i.e.*, from 103° to 79·5°.

The following interesting and amusing account of the eclipse observations of Prof. Lewis Swift, by a reporter of the *Rochester Democrat*, appears in the *New York Tribune*.

Prof. Lewis Swift returned from Denver, Col., Saturday evening, bringing splendid trophies of his skill as a searcher of the heavens. That his discovery was not duly reported by the Associated Press is chiefly owing to Prof. Swift's modesty in heralding the results of his labours and his desire to carefully determine the significance of his observations before making public announcement. Yesterday afternoon we visited Prof. Swift at his pleasant home in Ambrose Street, and learnt from him the story of his visit to Denver and observations of the total eclipse. Prof. Swift said:—"Up to the time of the eclipse the prospects for a clear day were very poor. The nights were clear, but it was cloudy, and rainy every afternoon. Sunday afternoon there was a clearing storm, with hail and drenching rain. Up to Sunday afternoon an unprecedented amount of rain had fallen in the region. On Monday morning there was not a cloud in the sky, and all predicted a clear day, and we had it. The final preparations were made as rapidly as possible. A. C. Thomas had arrived at the eleventh hour from Chicago with a telescope and spectroscope attachment. Prof. Hough had brought a small telescope with fine lines stretched across the object-glass, and a micrometer eyepiece, for the purpose of measuring the corona. I had secured from the Mayor the services of a police-officer to keep the grounds about the instruments clear from spectators. According to Washington predictions the eclipse was to commence at 4h. 7m. 50·4s. According to Prof. Colbert's calculations it would begin at 4h. 10m. 50s., Washington time—a difference of three minutes. Prof. Colbert's prediction, was proved to be very nearly correct. About half an hour before the eclipse was to

begin our party took their positions. I was about twenty feet to the south of Prof. Hough, who was in a group consisting of himself, Prof. Colbert, and Prof. Easterday, who used the telescope for observing the corona. To the west was a class of fifteen young ladies from Denver, instructed by Prof. Colbert to sketch the corona. South-east of my position Mr. Thomas was stationed.

"When arranging my instrument I made the post very low, exciting much comment by my companions. I told them I intended to lie on the ground during the observations, this being a position I had found the easiest in my experience of twenty years' comet-seeking. I spread a carpet on the earth and had a great advantage over the other members of the party, who were obliged to assume constrained positions, which tended to unsteadiness of vision. Seated by me was Daniel Drummond, with an accurate time-piece, set by the chronometer a few minutes before the first contact. E. D. Smith, an old acquaintance, whom I met in Denver, recorded the time of each event as I called it. Mr. Drummond is an experienced engineer, and counted the seconds with great accuracy.

"As I arranged my telescope for the first event the wind was blowing in fitful gusts from the south-east, shaking our instruments. To prevent my instrument from swaying I tied a long stick to it, about a foot above the eyepiece, the other end being braced against the ground and free to move only in one direction. This was a blunder to which I owe the discovery of a stranger, which I am inclined to think is Vulcan. As the sun moved the eye end of the telescope moved to the east. The stick would not allow any backward movement, and when I attempted to observe the sky to the east of the sun I could not. This confined my area of vision to a small distance west of the sun. But to return to the observation. My observation of the first contact was four seconds later than the observation of Prof. Colbert. The following is my record of events by Washington time:—

	h.	m.	s.
First contact	4	11	18
Bailey's beads	5	20	22
Beginning of totality	5	20	38
Corona first seen	5	23	17
End of totality	5	23	26
End of eclipse	6	26	35

"The watch was one second slow of the chronometer at the first contact, two seconds at the end of totality, and four seconds at the end of the eclipse. Before the eclipse began I had made up my mind to observe the general phenomena, the corona, protuberances, and Bailey's beads for about half a minute at the beginning of totality. I designed a minute and a half for a search for Vulcan, and the remainder, some forty odd seconds, to observe the phenomena at the end of totality.

"About one minute after totality two stars caught my eye about three degrees, by estimation, south-west of the sun. I saw them twice, and attempted a third observation, but a small cloud obscured the locality. The stars were both of the fifth magnitude, and but one is on the chart of the heavens. This star I recognised as Theta in Cancer. The two stars were about eight minutes apart. There is no such configuration of stars in the constellation of Cancer. I have no doubt that the unknown star is an intra-Mercurial planet, and am also inclined to believe that there may be more than one such planet. In 1859 the French astronomer Lescarbault claimed that he had seen an intra-Mercurial planet crossing the sun's disc. He related his discovery to Leverrier, who became a firm believer in the existence of such a planet. The perturbations of Mercury's orbit demand such a planet as Leverrier named Vulcan. The star I saw may have been the same that was seen by Prof. Watson, who was located at Rawlings, Wy. T.

"I possessed a comet eye-piece of very flat and large field and distinct to the very edge. It was made in this city, and to it and my blunder in failing to untie my instrument I owe my success. Prof. Colbert, of our party, also searched for Vulcan, but his field was not large. I saw but two protuberances, and those just at the end of totality. The advancing moon uncovered them. I had a view for at least two seconds of the sun's chromosphere at the same time. The chromosphere, by my measurement, is 2,000 miles in thickness. It is a layer of red-hot hydrogen surrounding the sun. The protuberances are projected from it.

"The corona was unusually extensive. It had never been seen so far extended. The greatest prolongation was in the direction of the moon's path across the sun, and as drawn by some of the parties extended on each side of the sun to a distance of more than three million miles. The pencils of light were radial mostly, though some of them were curved. I came away so quickly from Denver that I did not learn of the success of the other parties. In comparing notes with our party, Prof. Hough agreed with me in the measurement of the chromosphere. This measurement is made by calculating the time it takes the moon to pass over it. I learned of Prof. Watson's discovery the day after the eclipse. I have not seen him since he made the observation."

OUR ASTRONOMICAL COLUMN

WATSON'S SUSPECTED PLANET.—At the instance of M. Mouchez, the director of the Bureau des Calculs of the Observatory at Paris, M. Gaillot, who so long assisted Leverrier in the formation of his planetary tables, has examined how far the position of the object seen by Prof. Watson will accord with the more probable of the orbits which Leverrier inferred for a hypothetical planet, from the observations of suspicious spots in transit over the sun's disc. It may be remembered that their discussion led to a general formula, which was thus expressed by Leverrier; ν being the heliocentric longitude of the planet, k an indeterminate which might have values positive or negative, but necessarily whole numbers, and j the number of days reckoned from the beginning of the year 1750:—

$$\nu = 139^{\circ}\cdot94 + 214^{\circ}\cdot18\,k + (10^{\circ}\cdot901252 - 1^{\circ}\cdot972472\,k)\,j + (-5^{\circ}\cdot3 + 5^{\circ}\cdot5\,k)\cos.\,\nu.$$

M. Gaillot has found that, of the four possible orbits retained by Leverrier, corresponding to $k = -2, -1, 0,$ and $+1$, respectively, the first agrees the closest with the observation. With this value of k the diurnal motion is 14°·8462, the semi-axis major 0·164, and the period of revolution 24·25 days—less than the period of the sun's rotation. When the question of eccentricity is introduced, it is remarked that in the preferable orbit it is already very considerable, and comparable with that of the orbit of Mercury, and it is easy to demonstrate, to use M. Gaillot's words, "qu'il peut y avoir identité absolue entre la position observée et la position prévue." In fact, he finds that the agreement will be perfect if the eccentricity is assumed 0·14, and the longitude of the perihelion 74°. With regard to the inclination of the orbit to the ecliptic, M. Gaillot, from further consideration, supposes it may not exceed 7°. He notes that the most serious objection which opposes itself to the identification of the object observed, with a planet moving in the orbit indicated by Leverrier's formula, is that we should see but a very small part of the disc illuminated, and without denying that there is reason in this objection, M. Gaillot adds that Prof. Watson describes "as being of the fourth magnitude, a star the diameter of which may be comparable with that of Mercury, and which, in superior conjunction, may appear of the first magnitude." He further remarks that while it is not possible to decide with certainty upon the identity of

Prof. Watson's planet with that of which Leverrier has indicated the track, he believes he has shown that there is no incompatibility between the observed and hypothetical objects. If only one such planet exist between Mercury and the sun M. Gaillot points out that, in order to account for the accelerated motion in the perihelion of Mercury, its mass must be nearly equal to that of the latter—an inference drawn from Leverrier's table in vol. v. of the Paris *Annales*. An ephemeris extending to September 1 is appended to M. Gaillot's communication in the *Comptes Rendus* of August 5. Remarking that the assumed sidereal period of Prof. Watson's planet is 24·25 days, the synodical period is nearly twenty-six days, and accordingly we find by the ephemeris that the body should pass nearly at the same distance in longitude and latitude from the sun on August 24. But considering that this must hold during the next revolution whatever the period of any possible intra-Mercurial planet may be, it may be suggested that the most effectual plan of search will be to watch daily the vicinity so indicated with our larger instruments beyond the period at which the hypothetical planet should pass according to M. Gaillot's ephemeris. To set the equatorial it will be sufficient to subtract 9m. 50s. from the sun's right ascension at the proposed time of search, and to add to the sun's N.P.D. a quantity varying from 23′ on August 22, to 17′ on September 10.

A COMPANION OF α LYRÆ.—On several occasions during the last ten years, to our knowledge, attention has been directed to a star near α Lyræ in the *n.f.* quadrant, and suspicion of variability entertained, from the observer not having distinctly remarked it previously. An inquiry on the same point was lately addressed by a correspondent to Prof. Winnecke. The star is on an angle of about 42°, distance 139″. In October, 1870, it was a full magnitude fainter than the well-known Herschelian companion. Possibly some reader interested in the variable stars may be able to say if there is any reason to include the more distant star in this class of objects. In due course the direction of the proper motion of the large star will bring it immediately upon this *comes*, supposing there be no physical connection.

SCHMIDT'S "CHARTE DER GEBIRGE DES MONDES."—We hope next week to give some account of this most laborious and valuable work, which has been produced, through the liberality and scientific spirit of the Prussian government, in a style and with a perfection of arrangement that reflect the highest credit on all concerned. Probably no astronomical work could possess a greater degree of interest for amateurs generally, and—considering the attention paid to the examination of the moon's surface in this country—to British amateurs especially.

GEOGRAPHICAL NOTES

THE Arctic exploring ship *Alert* is being again fitted out for active duty, under the command of her old captain, Sir George Nares. She is intended for a voyage of surveying service principally in the South Pacific. Her first work will be an examination of the inner water leading from the Straits of Magellan to the Gulf of Peñas, along the seaboard of Chili; from this she will stretch across the South Pacific Ocean towards Fiji adding (*en route*) as far as practicable to our knowledge of the hydrography of the Low Archipelago, Society and Friendly Islands. After a few months spent in the neighbourhood of Fiji and in an examination of dangers lying in the track of navigation between that group and the Colony of New Zealand, she will, for the latter part of her voyage, be employed off the North Western Coast of Australia, principally in ascertaining the positions of, and as far as necessary charting, the various reefs and islets lying off the Australian continent, and between it and the ports of the Dutch Indies, at many of which reefs, &c., traffic has been for some time increasing in the search for trepang, pearls, and guano.

THE *Mittheilungen* of the Vienna Geographical Society, Nos. 6 and 7, contains a valuable "Culture-Map" of Asia Minor, exhibiting in a satisfactory manner the various zones of vegetation which mark that region recently brought into such intimate relations with this country. The map is by A. v. Schweiger-Lerchenfeld, who contributes also the explanatory text. Dr. Ziegler describes the important works carried on during 1877-8 by the Swiss correspondents of the Society, and Prof. Schmick contributes a paper on Ocean Currents.

FROM America we have No. 2, 1878, of the always interesting *Bulletin* of the American Geographical Society. A paper on "Japan, Geographical and Social," by the Rev. W. E. Griffis, contains the results of much research, as well as of personal observation, and is an important contribution to our knowledge of that country. Dr. Wright Hawkes discusses in an able and unprejudiced manner "The So-called Celtic Monuments of Britanny," his conclusion being that the evidence as to their origin is very conflicting. Mr. Jess Young, who was astronomer to Giles's trans-Australian expedition, gives an account of the results of his observations while crossing the great Australian desert.

THE Geographical Society of St. Petersburg intends to publish Karl Ritter's works in Russian in celebration of his jubilee.

WE learn that a new branch of the Russian Geographical Society, independent of those of Orenburg and Western Siberia, will shortly be opened at Tashkent.

WE have received from Williams and Norgate a neat and well-executed map of Cyprus, by Kiepert of Berlin, upon a sufficiently large scale to show distinctly the chief features of the island.

NOTES

PROF. MENDÉLEEFF is to be absent from his post in the St. Petersburg University for a year for the purpose of visiting Western Europe, where he will devote his time to the preparation of a large work on aëronautics. The work will contain a historical sketch of the subject, and expound its present condition from a scientific point of view.

THE appearance is announced of a biography of the late Prof. von Baer, by Dr. Stida, Professor in the Dorpat University. The autobiography of Baer appeared some years before his death, but embraced only his childhood and youth. The work of Dr. Stida is chiefly devoted to the scientific life of Baer, and contains a complete review of his works.

WE are glad to see that the *Times* is beginning to recognise the national importance of science-teaching in schools, and the necessity for our legislators being able to estimate the bearings of the various problems in physical science which are involved in the measures that come before them, in which the national welfare is involved. In a leading article on the meeting of the British Association the *Times* says that "We are living in a time when legislation is busy with physical matters, and is likely to become more so. The tendency of unscientific persons, especially when they are politicians, is to ignore the certainties which physical science furnishes, and hence to suppose that legislation about physical matters may properly be conducted upon a basis of compromise, like legislation about matters of opinion. It is very important that people who are not scientific themselves, and who never will be, should yet possess enough scientific knowledge to understand the difference which separates questions on which compromise is proper or expedient from those in which it would be fatal to the attainment of the desired result." The *Times* seems to us in-

clined to rate too highly the educational influences of the British Association on our legislators and on the general public. The rational conclusion to be drawn from the admissions in the passage we have quoted is that there ought to be some kind of scientific council which Government could consult in regard to measures involving questions of science. The British Association has done good service in helping to draw the attention of the public to the real nature of science, but it can never be a substitute for such a council as that which the most eminent of our men of science maintain would be the only effectual guarantee for enlightened legislation in scientific matters, and the establishment of which was recommended by the Duke of Devonshire's Commission. It is gratifying to find that the *Times* admits that "physical science affords an admirable means of mental training in schools," and we trust the day is not distant when it will be placed on a footing of equality with other branches of education. From another leader on Prof. Huxley's address we may infer that this chief representative of average British opinion has advanced from its obstinate opposition to the doctrines associated with the name of Darwin; indeed, the tone of the article to which we refer seems even more "advanced" than the address which was the occasion of it. It is comforting to find that, in scientific matters, at least, a better spirit is beginning to pervade the paper which is both an index and a leader of middle-class public opinion.

THE time of meeting of the German Naturalists and Physicians at Cassel has been changed from September 18–24 to September 11–18. This change has been caused by the fact that during the time originally fixed a series of military manœuvres are to take place which will cause a great influx of military men into Cassel, the lodging resources of which, it is feared, would not be commensurate with the requirements of a simultaneous meeting of the men of science and of war.

THE meeting of the French Association will not take place at the Palais des Beaux Arts, as it was originally contemplated, but in the rooms of the Lycée Saint Louis. The session begins to-day.

A SOMEWHAT curious discussion has been recently occupying the attention of the Paris Academy of Sciences. It originated in the publication by M. Berthelot, in the *Revue Scientifique* of July 20, of a series of laboratory notes by the late Claude Bernard, on alcoholic fermentation, in which the great physiologist came to conclusions opposed to those so long advocated by M. Pasteur. It was natural that M. Pasteur should endeavour to weaken the force of M. Bernard's experiments and conclusions. In the *séance* of July 22 he drew attention to the publication of the notes, and explained their apparent opposition to his theory by the statement that Bernard's method of working was to proceed to the investigation of every theory as if its opposite were true, thus submitting every point to a crucial test. He declared his intention of taking up Bernard's series of experiments and working them out from the latter's standpoint, in the confidence that the result would be entirely in favour of his (Pasteur's) theory of fermentation. At the next sitting of the Academy M. Pasteur stated that he had found that many changes had been made for typographical and other reasons in the notes as they appeared in the *Revue* as compared with the original MSS., though these changes do not seem materially to alter the sense of the "Notes." M. Berthelot rejoices that M. Pasteur intends to repeat Bernard's experiments, and whatever may be the result, science is likely to be a gainer. There at present the matter rests.

WE notice the death in Jena, on July 25, of the well-known botanist Prof. Christian Eduard Langethal. He was born at Erfurt in 1806. After completing his botanical studies at Jena he was for some time assistant to the famous agriculturist Prof. Schulze, and in 1835 teacher of natural sciences at Eldena. In 1839 he was called to a professorship at Jena, which he occupied up to the date of his death. Prof. Langethal was the author of several standard works, among others, "Geschichte der deutschen Landwirthschaft" (1846-56); "Lehrbuch der landwirthshaftlichen Pflanzenkunde" (1841-45; fifth edition, 4 vols. 1876); "Beschreibung der Gewächse Deutschlands" (1858); "Terminologie der beschreibenden Botanik;" and "Flora von Thüringen," issued in conjunction with Schenk and Schlechtendal.

THE model of the Gauss monument has just been finished by Prof. Schaper. The design is made after an original portrait of Gauss, in the possession of Göttingen University, and the monument itself is now to be executed in bronze at the atelier of Herr Gladenbeck, of Berlin. It will be erected at Brunswick, the birthplace of the great mathematician.

THE Royal Academy of Sciences at Munich has just elected to membership Prof. Krehl, of Leipzig, and Mr. Charles Darwin.

MEASURES are being taken for the foundation of a geological institute at St. Petersburg, which shall accomplish for the Russian empire what the Imperial Institute at Vienna has done for Austria. At present geological work is attempted only at the instigation of mining companies and the learned societies, and the want of unity in the efforts made for the development of Russian geology has long been painfully felt.

THE French Minister of Public Instruction has authorised the director of the newly created Central Meteorological Bureau to hire a hotel in the Rue de Varenne, in a populous part of Paris, where no observations can be taken, in which to establish the offices of his administration, which, within a few days, will be removed from the observatory. It is fair to state that Admiral Mouchez will not discontinue the taking of meteorological observations with the instruments established by Arago. It is pretty certain that the magnetical instruments established at a great expense by Leverrier will not be removed at a period so important in the history of terrestrial magnetism. We can state that new observers will be paid for that purpose, if necessary.

THE Meteorological Commission of Vaucluse again this year ascended Mont Ventoux. M. Mascart, the new director of the Meteorological Central Bureau, was one of the party, having come from Paris for that purpose. Simultaneous observations were taken at Orange, Carpentras, Avignon, and Apt. But the principal object of this scientific excursion was to determine the best manner of erecting the contemplated observatory at the top of this mountain, which is 1,919 metres above the level of the sea, and 1,692 above Apt, the nearest meteorological station.

THE Giffard captive balloon has become a great favourite amongst the visitors to Paris, as well as the Parisians themselves. The greatest number of ascents in one day has been seventeen, and the money taken has been 6,000*l.* in eighteen days, including three in which ascents could not take place, owing to the boisterous state of the weather. The charges are one franc for witnessing the ascents, and twenty francs for ascending.

THE Lords of the Committee of Council on Education have determined to award bronze medals to students who obtain a first-class in honours in any subject of science at the May examinations.

IN an Appendix to the Annual Report (for 1878) of the Lyceum of Valparaiso, Mr. Edwyn C. Reed gives an account of the progress he has made in commencing a Museum of Natural History for this Institution, which, if we understand rightly, is not intended to be simply for the instruction of the scholars of

the Lyceum, but for the City of Valparaiso generally. The new Museum does not appear to be well off for funds, but Mr. Reed has many friends and correspondents in this country who will be able to serve him by exchanges.

THE second marine excursion of the Birmingham Natural History and Microscopical Society to the Island of Arran, in the month of July last, proved most successful. Twenty-eight members, including six ladies, formed the party, who travelled by Pullman cars and family carriage by Midland railway, going by night and returning by day. A small steam yacht—the *Lizzie*—was chartered for a week. There were also botanical and geological excursions daily to the many interesting parts of the island. The results of the dredgings were most satisfactory, and a beautiful series of specimens was taken, including *Luidia fragillisima* and two or three Nudibranchs new to the locality. The towing-net—on an improved principle, devised by Mr. Henry Allport—was also used most successfully, and many interesting forms of marine life taken, notably *Bipinnaria* and *Pluteus*. The examination of these and other microscopic objects in the evenings in the ladies' drawing-room proved a great attraction. Preliminary reports have been made to the society and the specimens exhibited:—General, by Mr. Edmund Tonks, B.C.L., president, and Mr. Sam. Timmins, F.R.S.L.; Botanical, by Mr. John Morley, hon. sec.; Dredging Arrangements, Mr. John F. Goode; and Marine Zoology, by Mr. W. R. Hughes, F.L.S. The Geological Report, by the Rev. George Deane, D.Sc., F.G.S., was deferred. A full account of the proceedings will appear in an early number of the *Midland Naturalist*. The excursion extended from July 19 to 27, and a most interesting and enjoyable week was passed. A resolution was unanimously passed suggesting to the society that the next excursion should be to Falmouth.

WE have on several occasions drawn attention to the interesting department in the Paris Exhibition devoted to school equipments, and it is hopeful to find that in connection therewith, a *Times* Paris correspondent has discovered the success of the French in their efforts to impart to the nation a technical education. "One of the most interesting and instructive departments of the Exposition," the *Times* correspondent writes, "is that devoted to the illustration of the working and results of the system of French popular education both in Paris and in the Provinces. The foreign visitor who observes with admiration throughout the country the evidences of the general artistic and technical skill of the French workmen of every class will see in this Educational Department of the Exposition the key to the secret of that success. When will the corporation of London be able to match the interesting educational results here displayed by the sister municipality of Paris?"

UNDER the presidentship of Lord Hardwicke the opening meeting of the thirty-fifth annual congress of the British Archæological Association began on Monday at the ancient town and port of Wisbech.

ZOOLOGISTS will be glad to know that the "Rules for Zoological Nomenclature," drawn up by the late H. E. Strickland, F.R.S., at the instance of the British Association, have been reprinted. The "Notes" were prepared after consultation with many zoologists, British and foreign, and are now brought out under the care of Mr. P. L. Sclater. The publisher is Mr. Murray.

PROF. BROCA opened the International Congress of Anthropology at the Paris Exhibition by a short address, in which he pointed out the necessity of rigid observation as the only means of obtaining trustworthy data on which to build the science.

WE are glad to learn that the French balloon service has not een disorganised by the resignation of Col. Laussedat. The new head of the service is General Farr, who distinguished himself in the last Franco-German war in the northern part of France.

DR. ERNST, of Carácas, writes us that by an oversight in his note on the earthquake of Cúa (NATURE, vol. xviii. p. 130) the direction of the shock was not given. It came from E.N.E., or more exactly E. 15° N.

THE article on the Elasmotherium from which our description was obtained (vol. xviii. p. 387) appeared in No. 23 of the Russian journal *Niwa* for 1878, p. 411.

THE additions to the Zoological Society's Gardens during the past week include a Lion (*Felis leo*), a Patas Monkey (*Cercopithecus ruber*) from West Africa, presented by Mr. W. H. Wylde, s. s. *Agra*; a common Paradoxure (*Paradoxurus typus*) from India, presented by Mr. Edwin Etty Sass; two Common Buzzards (*Buteo vulgaris*), European, presented by Master Valentine Marks; two Herring Gulls (*Larus argentatus*), European, presented by Mr. Thomas Landseer; a Crested Ground Parrakeet (*Calopsitta novæ-hollandiæ*) from Australia, presented by Mrs. Parker; a many-zoned Hawk (*Melierax polyzonus*) from East Africa, presented by Mr. C. H. Fisher; a Copper-head Snake (*Cenchris centortrix*) from Pittsburg, U. S. A., presented by Dr. F. Painter, F.Z.S.; a Macaque Monkey (*Macacus cynomolgus*) from India, two Barbary Apes (*Macacus inuus*) from North Africa, two Beautiful Parrakeets (*Psephotus pulcherrimus*) from Australia, thirteen Greek Land Tortoises (*Testudo græca*) European, deposited; a Bladder-nosed Seal (*Cystophora cristata*) from the North Atlantic, six Common Kingfishers (*Alcedo ispida*) British Isles, purchased.

THE BRITISH ASSOCIATION

DUBLIN, *Tuesday*.

SINCE we last wrote the British Association week has come and gone with even more than its wonted rush and whirl of incessant engagements. That the meeting has been a successful one in every respect is unquestionable. Though no very original papers have been read or any great sensation excited in any section, as at Plymouth, by the telephone, yet the meetings have been above the average in general interest, the evening lectures and entertainments having been specially attractive, and the attendance extremely good. This meeting will always be memorable for the splendid address of the president, Dr. Spottiswoode.

The proceedings have been very fairly and fully reported in the local papers. Is it too much to hope that, ere long, the Association may see its way to utilising the energy now invariably displayed by the provincial press in giving to its members an early, full, and revised report of the proceedings of the meeting in a more convenient form than in the columns of a newspaper? We are aware that this question has often been mooted, and indeed it has not been untried, but for its permanent success a well-considered scheme is necessary, and doubtless the local press, as well as the sectional secretaries (more especially if some honorarium were attached to one secretary in each section) would gladly lend their aid. If we may judge by the constant inquiries for such a report that reach our ears at each meeting of the Association, it would seem to be a widely-felt want. Our own columns have, to a large extent, been opened to meet this need; but it is obvious that the constant pressure upon our space only permits a partial report of the proceedings, whilst the discussions upon the papers, often extremely valuable, have no permanent record, even in a condensed form.

There is another point upon which we may venture to say a word or two, and that is, the desirability of giving a little more attention to the fact that a large majority of

those present at the meetings of the Association have had no special scientific training, and to whom, therefore, almost the whole of the sectional proceedings are one continuous riddle. Would the actual usefulness of the Association to scientific men be in any way lessened by devoting a certain portion of the proceedings of each section at a specified time to papers specially prepared for an audience, not of specialists, but simply of intelligent men and women, and to reports on the progress of the various branches of science, couched in untechnical language? Would not such a course be a distinct gain in the diffusion of science, and in its permanent effect upon the town where the annual meetings are held; and would it not enable the general public to give a more hearty and sympathetic support to the scientific worker?

Let us now put on record a brief epitome of the principal events in the meeting which has just closed. On Wednesday night, August 14, Dr. Spottiswoode delivered his presidential address to a crowded audience, but, unfortunately, in a room only suited to the strongest lungs. The concert-hall of the Exhibition Palace was the only room available for the purpose, and the Association were fortunate in having chosen lecturers with such powerful voices as Mr. Romanes and Prof. Dewar, who subsequently delivered their discourses in the same place.

The first lecture, by Mr. Romanes, on Animal Intelligence, was admirably delivered and excited general interest by its lucid and masterly exposition of the psychological affinities between the mind of man and that of the lower animals.

The lecture by Prof. Dewar, on "Dissociation, or Modern Ideas of Chemical Action," delivered on the 19th, will be memorable for its magnificent display of experimental illustrations; the prodigious labour involved in the preparation for the successful execution and for rendering visible to an immense audience (as was the case) a multitude of novel and delicate experiments, generally seen only on a small scale, but here magnified to astonishing proportions, can only be known to those who have gone through a like, though lesser, toil.

Numerous *conversazioni* and private entertainments must leave upon the minds of the members a not unjust impression of the gaiety and hospitality of the citizens of Dublin in their corporate as well as in their private capacity. First there came an unusually brilliant *soirée* given by the Royal Dublin Society, many of the objects of interest in which were reproductions lent by the South Kensington Museum from the valuable loan collection of 1876. To the untiring exertions of Mr. J. H. Wigham, of the firm of Messrs. Edmundson, both on this occasion as well as on others, the hearty thanks of the Association are due. All the powerful machinery in actual use in first-class lighthouses for the purposes of illumination, as well as for signalling in fogs, was erected for the use of the Association in the spacious premises of the Royal Dublin Society, at the sole expense of the firm Mr. Wigham has made so well known.

On Friday evening the Rector and Vice-Rector of the Catholic University gave another *conversazione*. The brilliancy of the electric lights, derived from a Gramme machine, exhibited here on this and on subsequent occasions, delighted everyone. The phonograph was exhibited in the physical lecture-hall, songs were sung and poetry recited by this instrument with the most perfect success. In one instance a song which had been sung into the phonograph by a well-known Dublin vocalist was turned on, after the lapse of an hour, in the presence of a new audience, who had not heard the original, and not only were the words and the melody easily recognised, but those who were familiar with the style of the singer were able at once to tell whose voice it was that came forth thus wonderfully from the rotating cylinder. In another hall, specially darkened for the purpose, Mr. Spottiswoode's vacuum tubes were exhibited, to great advantage by means of a splendid induction coil made by Mr. H. Yeates, of London. It was shown, too, how the stratification of the electric light, in these tubes, may be unravelled by the aid of a rotating mirror, the character of the stratification changing most remarkably with every change in the strength of the current. These experiments were greatly facilitated by the use of a new form of Bunsen's bichromate of potash battery, lately devised by Dr. Molloy, Professor of Physics in the Catholic University, for general use in the laboratory. This battery, which consists of six large cells, is always ready for immediate use, and is equal in power to at least eight quart cells of Grove's battery.

The great hall of the University was laid out with refreshments on one side, while on the other a varied and most successful series of interesting and brilliant experiments, illustrating the phenomena of heat, light, sound, and electricity, offered an intellectual feast even more attractive to the great body of the visitors. Upwards of 700 guests were received during the evening, but, owing to the admirable arrangements, all were able to make their way through the several halls without any inconvenient pressure. Amongst the guests we noticed most of the distinguished English and foreign *savans*, the President of the Association and Mrs. Spottiswoode, Sir John and Lady Lubbock, Sir Joseph Hooker, Prof. Roscoe, Prof. Gladstone, &c.

We understand that it is to Dr. Molloy, the genial and accomplished Professor of Physics at, and Vice-Rector of the Catholic University, the Association is indebted for one of the pleasantest evenings during this meeting.

On Monday the President and Fellows of the Royal College of Surgeons gave a reception to the chief members of the Association, and on Tuesday evening an interesting *soirée*, open to the Association generally, was given by the Royal Irish Academy. The Lord Lieutenant and the Duchess of Marlborough were present both on Thursday evening at the Royal Dublin Society and on Tuesday at the Royal Irish Academy.

Saturday, as well as Thursday, was devoted to excursions, particulars of which we gave in a former impression.

At the general committee on Monday, Mr. Sorby, and other delegates, attended to invite the Association to meet at Sheffield, an invitation which was cordially and unanimously accepted. Dr. Allman was chosen president, and Swansea was fixed upon as the place of meeting for 1880. The officers of the Association were re-appointed, and the election of Mr. J. E. H. Gordon as assistant general secretary was confirmed. The retirement of Mr. Griffith from this post which he has so long and admirably filled, caused universal regret. We hope it may not be considered impertinent if, in conclusion, we also express our sense of the great loss which the Association has sustained in the resignation of Mr. Griffith, who, in spite of the many demands upon his time and patience, has combined a systematic and energetic discharge of his duties with the most calm and courteous demeanour during the fifteen years that he has filled the arduous post.

To-day the University of Dublin conferred the honorary degree of LL.D. on the following members of the Association:—Mr. W. Spottiswoode, Prof. H. J. S. Smith, Dr. Janssen, Prof. Maxwell Simpson, Prof. E. Roscoe, Prof. Alexander W. Williamson, Mr. Evans, Sir John Lubbock, Sir J. D. Hooker, Prof. W. H. Flower, Prof. Huxley, Sir Wyville Thomson, and Prof. J. Thomson.

(*By Telegram.*)

DUBLIN, *Wednesday*.

The attendance at the concluding general meeting has been considerably above the average, the total number present being 2,577, of which 1,959 had either Associa-

tion or ladies' tickets, whilst 110 new members joined. The total sum received by the treasurer for tickets was 2,605*l.* Last year the attendance was 1,229, and the sum taken 1,268*l.*

The following grants were made :—

	£
Mathematics and Physics.	
Cayley, Prof.—Calculation of Factor Tables for the Fifth and Sixth Millions (re-appointed)	150
Sylvester, Prof.—Tables of Fundamental Invariants of Algebraic Forms	50
Forbes, Prof. G.—Observation of Atmospheric Electricity at Madeira (renewed)	15
Haughton, Rev. Dr.—Tables of Sun-Heat Coefficients	30
Joule, Dr.—Determination of Mechanical Equivalent of Heat (renewed)	65
Forbes, Prof.—Instrument for Detecting Presence of Fire-damp in Mines	30
Ayrton, Mr.—Specific Inductive Capacity of a good Sprengel Vacuum	40
Glaisher, Mr.—Luminous Meteors	20
Gill, Mr. D.—Improvements in Astronomical Clocks	30
Chemistry.	
Roberts, Mr.—Composition and Structure of some of the less known Alkaloids (re-appointed)	25
Wallace, Dr.—Development of Light from Coal-gas of different qualities (re-appointed)	10
Adams, Prof. W. G.—Electrolysis of Metallic Solutions and Solutions of Compound Salts	25
Geology.	
Evans, Mr. John.—Exploration of Caves in Borneo	50
Hull, Prof.—Circulation of Underground Waters (re-appointed)	15
Godwin Austen, Mr.—Kentish Boring Exploration (renewed)	100
Evans, Mr. John.—Kent's Cavern Exploration (re-appointed)	100
Evans, Mr. John.—Record of Progress of Geology (re-appointed)	100
Haughton, Rev. Dr.—Fermanagh Caves Exploration (re-appointed)	5
Close, Rev. Maxwell.—Miocene Flora of Basalt of North of Ireland	20
Biology.	
Bate, Mr. Spence C.—Marine Zoology of South Devon	20
Stainton, Mr.—Record of Zoological Literature (re-appointed)	100
Foster, Dr. M.—Table at the Zoological Station, Naples (re-appointed)	75
Brooke, Sir Victor.—Illustrations for a Monograph on the Mammoth	17
Sclater, Mr. P. L.—Natural History of Socotra	100
Rolleston, Prof.—Exploration of Bone Caves in South Wales (partly renewed)	50
Fox, General Lane.—Exploration of Ancient Earthworks (re-appointed)	25
Fox, General Lane.—Excavation at Port Stewart, and elsewhere in the North of Ireland	15
Statistics and Economic Science.	
Farr, Dr.—Anthropometric Committee (re-appointed)	50
Mechanics.	
Thomson, Sir W.—Datum Level of the Ordnance Survey (re-appointed)	10
Froude, Mr. W.—Instruments for Measuring the Speed of Ships (renewed)	50
Napier, Mr. J. R.—Steering of Screw Steamers (re-appointed)	10
Thomson, Sir W.—Tidal Observations in the English Channel (re-appointed)	10

REPORTS.

Report of the Committee, consisting of Prof. Cayley, Dr. Farr, Mr. J. W. L. Glaisher, Dr. Pole, Prof. Fuller, Prof. A. B. W. Kennedy, Prof. Clifford, and Mr. C. W. Merrifield, appointed to consider the Advisability and to estimate the Expense of constructing Mr. Babbage's Analytical Machine, and of printing Tables by its means. Drawn up by Mr. Merrifield.—We desire in the first place to record our obligations to General Henry Babbage for the frank and liberal manner in which he has assisted the Committee, not only by placing at their disposal all the information within his reach, but by exhibiting and explaining to them, at no small loss of time and sacrifice of personal convenience, the machinery and papers left by his father, the late Mr. Babbage. Without the valuable aid thus kindly rendered to them by General Babbage it would have been simply impossible for the Committee to have come to any definite conclusions, or to present any useful report.

We refer to the chapter in Mr. Babbage's "Passages from the Life of a Philosopher," and to General Menabrea's paper, translated and annotated by Lady Lovelace, in the third volume of "Taylor's Scientific Memoirs," for a general description of the analytical engine.

The Report then, in Section I., contains an account of the general principles of calculating engines, and proceeds :—

II. *Special Characteristics of Mr. Babbage's Analytical Engine.*—1. *The Mill.*—The fundamental operation of Mr. Babbage's analytical engine is simple addition. This and the other elementary rules of subtraction, multiplication, and division, and all combinations of these, are performed in what is called "*the mill.*" All the shifts which have to take place, such as changing addition into subtraction by throwing a reversing train into gear, or the shift of the decimal place, carrying and borrowing, and so forth, are effected by a system of rotating cams acting upon or actuated by bell-cranks, tangs, and other similar devices commonly used in shifting machinery, sometimes under the name of clutches or escapements. These clutches and bell-cranks control the purely additive and carrying processes effected in the additive trains described in the note to Section I., and, *being themselves suitably directed*, secure that the proper processes shall be performed upon the proper subject-matter of operation, and duly recorded, or used, as may be required.

2. *The Store.*—A series of columns, each containing a series of wheels, constitutes the store. This store, which may be in three or more dimensions, both receives the results of operations performed in the mill, and serves as a store for the numbers which are to be used in the mill, whether as original or as fresh subjects of operation in it. Each column in the store corresponds to a definite number, to which it is set either automatically or by hand, and the number of digits in this number is limited by the number of wheels carried on the shaft of the column. The wheels gear into a series of racks, which can be thrown into or out of gear by means of the cards.

3. *Variable Cards.*—All the numbers which are the subject of operation in the mill, whether they are the result of previous operations therein, or new numbers to be operated upon for the first time, are introduced to it in the form of Jacquard[1] cards, such as are used in weaving. One set of wires or axes transfers the numbers on these cards to the subject of operation in the mill, exactly as similar cards direct which of the warp threads are to be pushed up, and which down, in the Jacquard loom. The mill itself punches such cards when required.

4. *Operation Cards.*—A different set of cards selects and prescribes the sequence of operations. These act, not upon the number wheels of the mill or store, but upon the cams and clutches which direct the gearing of these wheels and trains. Thus, in such an operation as $(a\,b + c)\,d$, we should require :—

1st, four variable cards with the numbers a, b, c, d.

2nd, an operation card directing the machine to multiply a and b together.

3rd, a record of the result, namely, the product $a\,b = p$, as a fifth variable card.

4th, an operation card directing the addition of p and c.

5th, a record of the result, namely, the sum $p + c = q$, as a sixth variable card.

[1] In a letter written by Mr. Babbage to Arago in December, 1839, the following explanation of the use of these cards is given. It probably conveys the idea in the fewest words possible. It is only necessary to add that their twofold employment embodies the separation of the symbols of operation from those of quantity. "You are aware that the system of cards which Jacquard invented are the means by which we can communicate to a very ordinary loom orders to weave any pattern that may be desired. Availing myself of the same beautiful invention, I have by similar means communicated to my calculating engine orders to calculate any formula, however complicated; but I have also advanced one stage further, and I have communicated through the same means orders to follow certain laws in the use of those cards, and thus the calculating engine can solve any equations, eliminate between any number of variables, and perform the highest operations of analysis."

6th, an operation card directing the machine to multiply q and d together.

7th, a record of the result, namely, the product $q\,d = p_2$, either printed as a final result or punched in a seventh variable card.

III. *Capability of the Engine.*—It has already been remarked that the direct work of the engine is a combination and repetition of the processes of addition and subtraction. But in leading up to any given datum by these combinations, there is no difficulty in ascertaining tentatively when this datum is reached or about to be reached. This is strictly a tentative process, and it appears probable that each such *tentamen* requires to be specially provided for, so as to be duly noted in the subsequent operations of the machine. There is, however, no necessary restriction to any particular process, such as division; but any direct combination of arithmetic, such as the formation of a polynomial, can be made to lead up to a given value in such a manner as to yield the solution of the corresponding equation. In any such process, however, it is evident that there can be only (to choose a simile from mechanism) one degree of freedom; otherwise the problem would yield a locus, indeterminate alike in common arithmetic, and as regards the capabilities of the machine. The possibility of several roots would be a difficulty of exactly the same character as that which presents itself in Horner's solution of equations, and the same may be said of imaginary roots differing but little from equality. These, however, are extreme cases, with which it is usually possible to deal specially as they arise, and they need not be considered as detracting materially from the value of the engine. Theoretically, the grasp of the engine appears to include the whole synthesis of arithmetic, together with one degree of freedom tentatively. Its capability thus extends to any system of operations or equations which leads to a single numerical result.

It appears to have been primarily designed with the following general object in view: to be coextensive with numerical synthesis and solution, without any special adaptation to a particular class of work, such as we see in the difference engine. It includes that, *à majori*, and it can either calculate any single result or tabulate any consecutive series of results just as well. But the absence of any specialty of adaptation is one of the leading features of the design.

Mr. Babbage has also considered the indication of the passage through infinity as well as through zero, and also the approach to imaginary roots. For details upon these points we must refer to his "Passages from the Life of a Philosopher."

IV. *Present State of the Design.*—The only part of the analytical engine which has yet been put together is a small portion of "the mill," sufficient to show the methods of addition and subtraction, and of what Mr. Babbage calls his "anticipating carriage." It is understood that Gen. Babbage will (independently of this report) publish a full account of this method. No further mention of it will therefore be made here.

V. *Probable Cost.*—Without attempting any exact estimate, we may say that it would surprise us very much if it were found possible to obtain tenders for less than 10,000*l.*, while it would pretty certainly cost a considerable sum to put the design in a fit state for obtaining tenders. On the other hand it would not surprise us if the cost were to reach three or four times the amount above suggested.

Section VI. refers to *Strength and Durability*, and VII. to *Probable Utilisation of the Analytical Engine.*

VIII. *Possible Modification of the Engine.*—Without prejudging the general question referred to us as to the advisability of completing Mr. Babbage's engine in the exact shape in which it exists in the machinery and designs left by its inventor, it is open to consideration whether some modification of it, to the sacrifice of some portion of its generality, would not reduce the cost and simplify the machinery so as to bring it within the range of both commercial and mechanical certainty. The "mill," for example, is an exceedingly good mechanical arrangement for the operations of addition and subtraction, and with a slight modification, with or without store-columns, for multiplication. We have already called attention to the imperfection of the existing machines, which show weakness and occasional uncertainty. It is at least worth consideration whether a portion of the analytical engine might not thus be advantageously specialised so as to furnish a better multiplying machine than we at present possess. This, we have reason to believe, is a great desideratum both in public and private offices, as well as in aid of mathematical calculators.

Another important desideratum to which the machine might be adapted without the introduction of any tentative processes (out of which the complications of the machinery chiefly arise) is the solution of simultaneous equations containing many variables. This would include a large part of the calculations involved in the practical application of the method of least squares. The solution of such equations can always be expressed as the quotient of two determinants, and the obtaining this quotient is a final operation, which may be left to the operator to perform by ordinary arithmetic, or which may be the subject of a separate piece of machinery, so that the more direct work of forming the determinant, which is a mere combination of the three direct operations of addition, subtraction, and multiplication, may be entirely freed from the tentative process of division, which may thus be prevented from complicating the direct machinery. In the absence of a special engine for the purpose, the solution of large sets of simultaneous equations is a most laborious task, and a very expensive process indeed, when it has to be paid for, in the cases in which the result is imperatively needed. An engine that would do this work at moderate cost would place a new and most valuable computing power at the disposal of analysts and physicists.

Other special modifications of the engine might also find a fair field for reproductive employment. We do not think it necessary to go into these questions at any great length, because they involve a departure, in the way of restriction and specialisation, from Mr. Babbage's idea, of which generality was the leading feature. Nevertheless, we think that we should be guilty of an omission if we were to fail to suggest them for consideration.

IX. *General Conclusions, and Recommendation.*—1. We are of opinion that the labours of Mr. Babbage, firstly on his Difference Engine, and secondly on his Analytical Engine, are a marvel of mechanical ingenuity and resource.

2. We entertain no doubt as to the utility of such an engine as was in his contemplation when he undertook the invention of his analytical engine, supposing it to be successfully constructed and maintained in efficiency.

3. We do not consider that the possibilities of its misuse are any serious drawback to its use or value.

4. Apart from the question of its saving labour in operations now possible, we think the existence of such an instrument would place within reach much which, if not actually impossible, has been too close to the limits of human skill and endurance to be practically available.

5. We have come to the conclusion that in the present state of the design of the engine it is not possible for us to form any reasonable estimate of its cost, or of its strength and durability.

6. We are also of opinion that, in the present state of the design, it is not more than a theoretical possibility; that is to say, we do not consider it a certainty that it could be constructed and put together so as to run smoothly and correctly, and to do the work expected of it.

7. We think that there remains much detail to be worked out, and possibly some further invention needed, before the design can be brought into a state in which it would be possible to judge whether it would really so work.

8. We think that a further cost would have to be incurred in order to bring the design to this stage, and that it is just possible that a mechanical failure might cause this expenditure to be lost.

9. While we are unable to frame any exact estimates, we have reason to think that the cost of the engine, after the drawings are completed, would be expressed in tens of thousands of pounds at least.

10. We think there is even less possibility of forming an opinion as to its strength and durability than as to its feasibility or cost.

11. Having regard to all these considerations, we have come, not without reluctance, to the conclusion that we cannot advise the British Association to take any steps, either by way of recommendation or otherwise, to procure the construction of Mr. Babbage's analytical engine and the printing tables by its means.

12. We think it, however, a question for further consideration whether some specialised modification of the engine might not be worth construction, to serve as a simple multiplying machine, and another modification of it arranged for the calculation of determinants, so as to serve for the solution of simultaneous equations. This, however, inasmuch as it involves a departure from the general idea of the inventor, we regard as lying outside the terms of reference, and therefore perhaps rather for the consideration of Mr. Babbage's representatives than ours.

We accordingly confine ourselves to the mere mention of it by way of suggestion.

Third Report of the Committee, consisting of Dr. Joule, Prof. Sir W. Thomson, Prof. Tait, Prof. Balfour Stewart, and Prof. Maxwell for the Determination of the Mechanical Equivalent of Heat.—Dr. Joule has published a paper giving *in extenso* the experiments summarised in the last two reports, in the *Philosophical Transactions* of the Royal Society, where was published his former paper in 1850. The new result which confirms the old one, gives 772·55 foot pounds as the equivalent at the sea-level, and the latitude of Greenwich of the heat which can raise a pound of water, weighed *in vacuo*, from 60° to 61° F. of the mercurial thermometer where the permanent freezing point is called 32°, and the permanent boiling point of water under a barometrical pressure of 30 inches of mercury raised to 60° F. is 212°. The work at present in hand is a more accurate investigation of the true position of the freezing and boiling points of the thermometer when cleared from the effects of the imperfect elasticity of the glass of which they are constructed. The correction to the above equivalent which may thus accrue, is not expected to be of considerable amount.

Report of the Committee appointed for the purpose of inquiring into the possibility of establishing a "Close Time" for Indigenous Animals.—The Committee being dissatisfied with certain points in the Report of the Scottish Fishery Commissioners, addressed a letter to the Home Secretary, calling attention to the following points:—

"I. That conclusions Nos. 2 and 3 of the Commissioners, viz., that 'Legislation in past periods has had no appreciable effect,' and that 'Nothing that man has yet done, and nothing that man is likely to do, has diminished, or is likely to diminish, the general stock of herrings in the sea,' if correct, are absolutely contradicted by conclusion No. 13, which recommends that 'The Sea-Birds Preservation Act, protecting gannets and other predaceous birds which cause a vast annual destruction of herrings, should be repealed in so far as it applies to Scotland.'

"II. That conclusion No. 1, stating that 'The herring-fishery on the coast of Scotland as a whole has increased and is increasing,' clearly shows that there can be no necessity for the step recommended in conclusion No. 13 as above cited.

"III. That conclusion No. 13 seems to have been arrived at from exaggerated or incorrect information, as will appear from the following considerations:—The number of gannets on Ailsa is estimated ('Report,' p. xi.) at 10,000, and a yearly consumption of 21,600,000 herrings is assigned to them; while the Commissioners assume that there are '50 gannets in the rest of Scotland for every one on Alisa,' and on that assumption declare that the total destruction of herrings by Scottish gannets is more than 1,110,000,000 per annum. This is evidently a miscalculation; for, on the premises, this last number should be 1,101,600,000, a difference of more than 8,000,000.

"But, more than this, supposing the figures at the outset are right, it appears to the Close-Time Committee that the succeeding assumption of the Commissioners must be altogether wrong; at any rate, there is no evidence adduced in its support, and some that is contradictory of it.

"The number of breeding-places of the gannet in the Scottish seas has long been known to be five only, as, indeed, is admitted by one of the Commissioners (Appendix No. 2, p. 171; and the evidence of Capt. M'Donald, which is quoted in a note to the same passage, while estimating the Ailsa gannets at 12,000 in 1869 (not 1859, as printed), puts the whole number of Scottish gannets at 324,000 instead of 510,000, which there would be at the rate of 50 in the rest of Scotland for one on Ailsa, according to the Commissioners' assumption.

"Moreover, 50,000 of these 324,000 birds, or nearly one-sixth, are admitted by this same Commissioner to be 'of great value to the inhabitants' of St. Kilda, and, indeed, they are of far greater value to them than any number of herrings, since it is perfectly well known that the people of St. Kilda could hardly live without their birds; therefore this 50,000 must be omitted from any estimate of detriment. Deducting, then, 50,000 from Capt. M'Donald's 324,000, we have 274,000, and these, at the Commissioner's estimate, would consume 600,060,000 herrings instead of the 1,110,000,000 alleged by the report, and, therefore, nearly 200,000,000 fewer than the Commissioners' estimate of the annual take of the Scottish fisheries (800,000,000)—25 per cent. less instead of 37 per cent. more.

"Hitherto the supposition of the report, that the gannets frequent the Scottish seas all the year round, has been followed; but the Close-Time Committee begs leave to observe that, as a matter of fact, these birds are not there in force for more than half the year.

"This, then, will require another abatement to be made. Not to exaggerate the case, the Committee assumes them to frequent these waters seven months, or seven-twelfths of a year. This will make their annual capture of herrings 350,350,000, instead of the more than 1,110,000,000 of the Commissioners, being nearly 700,000,000, or much less than one-third, fewer.

"IV. That in all the evidence received and published by the Commissioners only two witnesses allege that any harm has resulted to the fisheries from the Sea-Birds Protection Act. Of these, the first, Robert M'Connell, presented a petition from the fishermen of Girvan, in which it is stated (p. 145) that 'no legislation is called for or required;' while another witness from the same place, John Melville (a fishery officer), declares (at p. 146) that 'The fishery has very much increased this last year. Recent years have also shown a gradual increase. The increase is partly due to the increased machinery and partly to the increase in the number of herrings.'

"The second witness unfavourable to the Act, John M'William (an Inspector of Poor), speaks (pp. 147-49) only from personal knowledge acquired between 1833 and 1853, when he ceased to be a fisherman, and not from any recent experience. He can therefore scarcely be held competent to give an opinion of his own as to whether the Sea Birds Protection Act (passed in 1869) has injured the fisheries. Another witness recommends the repeal of this Act; but he, Hugh MacLachlan, expressly states (p. 143) that he 'thinks the cause of the decrease [in the numbers of herrings taken] is the catching immature fish;' and the remedy he proposes is the adoption of a strict Close Time.

"V. That, on the other hand, the utility of sea-birds in pointing out the situation of shoals of herrings and other fish is not only generally notorious, but is even admitted in the Report (pp. 57 and 175).

"VI. That if the Sea-Birds Act be repealed on the grounds alleged for Scotland, its repeal for England and Ireland must logically follow; and this Committee trusts that no steps may be taken to repeal the Act for Scotland."

In view of any proceedings which may be taken in the Session of 1879 in regard to the recommendations of the Scottish Herring-Fishery Commissioners, as well as on general grounds, the Committee urges its reappointment.

SECTION A.—MATHEMATICAL AND PHYSICAL.

Note on the Pedetic Action of Soap, by Prof. W. Stanley Jevons.—Since the publication in the *Quarterly Journal of Science* for April, 1878, of my paper on Pedesis, or the so-called Brownian movement of microscopic particles, it has been suggested to me that soap would form a good critical substance for experiment in relation to this phenomenon. It is the opinion of Prof. Barrett, and some other physicists, that the movement is due to surface tension, whereas, I believe that chemical and electromotive actions can alone explain the long-continued and extraordinary motions exhibited by minute particles of almost all substances under proper conditions. Soap considerably reduces the tension of water in which it is dissolved, without much affecting (as is said) its electric conductibility. If, then, pedesis be due to surface-tension, we should expect the motion to be killed, or much lessened when soap is added to water.

Having tried the experiment, I find that the result is of the opposite character to what Prof. Barrett anticipated. With a solution of common soap the pedetic motion becomes considerably more marked than before. I have observed this result not only with china clay and some other silicates, but also with such comparatively inert substances, as the red oxide of iron, chalk, and even the heavy powder of barium carbonate. The last-named substance, one of those which we should least expect to dance about of its own accord, gave a beautiful exhibition of the movement when mixed with a solution of about 1 per cent. of soap, and viewed with a magnifying power of 500 or 1,000 diameters.

The correctness of this result was also tested by observing the suspending power of solutions of soap-solution compared with water. If a little china clay be diffused through common impure water, that, for instance, of the London Water Companies, the greater part of the clay will soon be seen to collect together in small flocks and fall to the bottom in two or three hours, the water being almost clear. However, if about 1 per

cent. be dissolved in the water, the behaviour of the clay is quite different. The larger particles soon subside, but the smaller ones remain diffused through the liquid for a long time, giving it a milky appearance, quite different from the flocky and grainy appearance of the common water; if 1 per cent. of sodium carbonate be dissolved in common water, and china clay be mixed therewith, the subsidence of the clay is still more rapid, owing, as I have explained, to the increase in the electric conductivity of the fluid, and the consequent decrease of pedesis. But I now find that if soap be added at the same time, pedesis is not destroyed but considerably increased, and the clay remains a long time in suspension, two or three days at least.

These facts give a complete explanation of the detergent power of soap. It has long seemed to me unaccountable that for cleansing purposes the comparatively neutral soap should be better than the alkaline carbonate by itself; we are told that the alkali is but feebly combined with the stearic or other fatty acids. But why combine it at all if we need only the alkaline power of the base? The fact is that the detergent action of soap is due to pedesis, by which minute particles are loosened and diffused through the water so as to be readily carried off. Pure rain or distilled water has a high cleansing power, because it produces pedesis in a high degree. The hardness of impure water arises from the vast decrease of pedesis due to the salts in solution. Hence the inferior cleansing power of such water. If alkaline salts be added, dissolved in water, it becomes capable of acting upon oleaginous matter, but the pedetic power is lessened, not increased. But if soap be added also, we have the advantage both of the alkali dissolving power, and of the pedetic cleansing power. At the same time we have a clear explanation why silicate of soda is now largely used in making soap; for I have shown, in the paper referred to, that silicated soda is one of the few universal substances which increase the pedetic and suspensive power of water.

I believe that the detergent power of soap and water is one of the many important phenomena which may be explained by the study of pedesis, and I propose to follow up the investigation of this movement in regard to the several substances which tend to increase it.

Motions produced by Dilute Acids on some Amalgam Surfaces, by Robert Sabine.—The author finds, when a drop of very dilute acid is placed upon the clean and newly filtered surface of a rather rich amalgam of some metal which is positive to mercury, that the drop does not lie still as it would do upon pure mercury, but sets itself into an irregular jerky motion. This is the case with copper, zinc, antimony, tin, and lead amalgams. But if instead of these amalgams those of platinum, gold, and silver are used—these latter metals being negative to mercury—the drop of acid water lies quite still. The acids tried were sulphuric, hydrochloric, oxalic, and acetic, which behaved similarly but in different degrees. When the experiment is made in an atmosphere of oxygen the movements upon the amalgams of the positive metals are increased; but in hydrogen, carbonic acid, nitrogen, and coal-gas the motions are instantly arrested.

The author concludes that the motions result from an alternate play of deoxidation of the mercury underneath the acid by electrolysis, due to the currents of small floating particles of the positive metal causing the drop to contract, and of oxidation of the surface outside the acid-drop causing it to re-expand.

On Certain Phenomena accompanying Rainbows, by Prof. Silvanus P. Thompson.—The author narrated several instances of rainbows seen chiefly in Switzerland, where radial streaks of light devoid of colour were observed within the primary and without the secondary bow. The explanation suggested was as follows:—The wedge-shaped radial streaks are beams of sunlight, which become visible by diffuse reflection from particles of matter in their path, just as the apparently divergent beams of sunrise or sunset become visible. These "beams" being practically parallel to one another, appear to converge in the point exactly opposite to the sun by perspective, or, in fact, just as the parallel beams of sunset appear divergent. Since the rainbow has for its centre the point opposite the sun, such beams must have positions radial with respect to the bow. They resemble, therefore, the *rayons du crépuscule* occasionally seen in the east at sunset; they had never been observed crossing the dark span between the primary and secondary bows. A similar phenomenon of rays might sometimes be seen in sunlight, when the shadow of the observer fell upon a slightly turbid lake or river.

SECTION B.

CHEMICAL SCIENCE.

OPENING ADDRESS BY THE PRESIDENT, PROF. MAXWELL SIMPSON, M.D., F.R.S.

MY position here is a highly honourable, but by no means a comfortable one. Naturally you expect to hear from me something new about the science which occupies the attention of this section, and I have the miserable feeling that I must disappoint you. How can I possibly find a fact in chemistry with which you are not already acquainted? If, in order to cater for you, I go to France, Germany, Russia, or America, I find the abstractors of the Chemical Society have been there before me, and have swept everything of value into their journal. Chemists are now kept perfectly acquainted with the progress of science in every part of the world, and therefore the *raison d'être* of this address, so far as announcing the discoveries of the year is concerned, has passed away. I therefore propose instead of giving you a concentrated essence of the last twelve numbers of the *Journal* of the Chemical Society, to bring before you the claims of this science to a place in general education, and the claims of original research to a place in the curriculum for higher degrees in our universities.

I have been devoted to chemistry all my life. It has been my business and my pleasure. The longer I live the more deeply am I impressed with the advantages to be derived from its study, and I am anxious that these advantages should be shared by the rising generation.

Whether we take into account the value of the knowledge acquired, the discipline of the intellectual faculties in acquiring that knowledge, or the effect on the character, surely we have a right to give the study of this science a prominent place in our schools and colleges. It would be difficult to over-estimate the value and extent of the knowledge we derive from chemistry. Without it we can know nothing about the air we breathe, the water we drink, or the food we eat; we cannot understand the processes of combustion, respiration, fermentation, putrefaction, or the endless chemical changes which are continually in operation around us, and which affect our lives for good or for evil. In a word, the whole of the phenomena of nature must for ever remain to us, more or less, an inscrutable mystery.

Again, is it not desirable that we should have some acquaintance with the chemical arts, from which we derive so many of our comforts and luxuries? Should we not know something of the arts of photography, dyeing, metallurgy—something of the manufacture of glass and china, and of the thousand beautiful things that are constantly in our hands? Not only is the knowledge we obtain from chemistry very considerable in itself, but it furnishes us with a key which enables us to unlock vast stores of knowledge contained in several other sciences—these are, physics, geology, mineralogy, physiology, and I may now add, astronomy. Physics and chemistry are so intimately connected that it is difficult to say where the one begins and the other ends. The help that chemistry gives to physics is shown by the numbers of chemists who have distinguished themselves as physicists. I may mention a few belonging to our own time—Andrews, Bunsen, Faraday, Frankland, Graham, Guthrie, and Regnault.

With regard to mental discipline, the mind of the student is exercised in both the inductive and deductive methods of reasoning. His original faculties are stimulated by the consciousness that he can in many cases readily test the worth of his ideas by experiment. With inexpensive apparatus and a good balance, the intelligent student can make out for himself some of the laws and many of the facts of the science, and, it may be, also add to them. He glides insensibly from the known to the unknown. Indeed his spirit of inquiry demands, in most cases, to be curbed rather than spurred. Some students are constantly finding out new methods of analysis or discovering the precious metals in impossible places.

The readiness with which we can cross over into the *terra incognita* of chemistry and make little explorations there, constitutes, in my opinion, the great charm of this science, and, to a great extent, its value as an educational agent. What I wish to insist upon is that the student of chemistry can reach the field of original work sooner than the student of most other sciences. Once he commences original research the development of his intellectual faculties rapidly progresses. His imagination is daily exercised in propounding new theories and devising experiments in order to ascertain their truth or

falsehood. And what more valuable intellectual training can there be than the habit of subjecting our ideas to the test of inexorable experiment? In the world outside chemistry we are, alas! too ready to take things for granted. The chemist's motto is *prove all things*. The ancients adopted a different method: they assumed certain principles and reasoned from them. They therefore did little in science.

Chemistry promotes in a remarkable manner accuracy, thoroughness, and circumspection. An organic analysis requires six weighings: if any one of these is inaccurate, the results are worthless. A qualitative test carelessly applied may cause us, in a research, to waste months in the pursuit of a phantom or Will-o'-the-Wisp which can have no corporeal existence. If we have to employ absolute alcohol in our experiments, we must not be satisfied with going through the ceremony of making it absolute, but we must assure ourselves that it *is* absolute. Unless we are sure of every step in our research, our results become doubtful, and therefore of no value.

On the circumspection, also, of the original worker large demands are made. The avenues by which error may creep in and vitiate his results are very numerous. These he must foresee, and endeavour to close up. Laboratory work teaches us to use our senses aright, sharpens our powers of observation, and prevents us from reasoning rashly from appearances. It also promotes manual dexterity, and trains the hands to work in subordination to the head.

Perhaps in no other science is the student so deeply impressed with the order and economy of nature, the immutability of her laws, and the exactness of her operations. These impressions will, no doubt, in after life impart seriousness to his character, and save him from the adoption of many a wild theory.

I come now to the effect of original work on the character. Many virtues are necessary to the chemist—courage, resolution, truthfulness, and patience. He is often obliged to perform experiments which are attended with great danger, and no man can hope to fight long with the elements without carrying away many a scar. Sometimes fatal accidents occur. Many years ago Mr. Hennel, of the Apothecaries' Hall, London, lost his life by the explosion of a fulminating powder which he was preparing for the East India Company. And many of us recollect the sad death of young Mr. Chapman, a distinguished chemist whom I had the pleasure of knowing, who was literally blown to atoms while working in the Hartz Mountains on a new dynamite which he had himself discovered. I must tell the ladies, however, that accidents are not always so disastrous, but that often one may escape with merely the loss of an eye. But the chemist must not be discouraged by fear of accident, neither must he be disheartened by the temporary failure of his experiments, nor at the slowness of his processes. Bunsen was obliged to evaporate forty-four tons of the waters of the Dürcheim springs in order to obtain 200 grains of his new metal, cæsium. It took Berthelot several months to form, by a series of synthetical operations, an appreciable quantity of alcohol from water and carbon, derived from carbonate of baryta. Many years ago, in the laboratory of Wurtz—my honoured master—a poor student, whom I knew, was carrying from one room to another a glass globe which contained the product of a month's continuous labour, when the bottom of the globe fell out, and the contents were lost. Nothing daunted, he recommenced his month's work, and brought his research to a successful issue.

Above all things, the chemist must be *true*. He must not allow his wishes to bias his judgment or prevent him from seeing his researches in their true light. He must not be satisfied that his results appear true, but he must believe them to be true; and having faithfully performed his experiments, he must record them faithfully. He may often be obliged to chronicle his own failures and describe operations that tell against his own theories, but this hard test of his truthfulness he must not shrink from.

But I must not weary you with the virtues of the chemist. If I have succeeded in showing that the pursuit of this science tends largely to develop the intellect and discipline the character, I think I have done something for chemistry. We are told by Bishop Butler that "habits of virtue acquired by discipline are improvement in virtue, and improvement in virtue must be advancement in happiness."

I am glad to see that the importance of original research as a part of higher education is at last beginning to be recognised in this country. The Royal University Commission at Oxford has recently recommended that candidates for the higher degrees in science shall in that university be required in future to work out an original investigation. In Germany, where education has been so long and so well understood, original work has been, for at least the last half century, a *sine quâ non* for a degree. Another admirable rule exists in that country, the adoption of which in Great Britain might go far to wash out the stain from our islands, of not having contributed our fair quota to the advancement of human knowledge. It is this—the Germans make a point of securing invariably that their scientific chairs shall be filled by men who have already distinguished themselves by their discoveries. The professor, on his appointment, naturally desires to continue his investigations, and endeavours to secure, and usually succeeds in securing, the assistance of his pupils. This is a mutual advantage. The professor is able to do more work for science, and the student, on his part, learns to conduct for himself an original investigation. Hence there is always a rising generation of original workers in Germany, who turn out papers more or less meritorious with the rapidity of a Walter's press. They are stimulated by the hope of one day arriving themselves at a professor's chair, the path to which they are well assured is only through the toilsome field of original work. But I must not wrong the German student by the implication of a purely selfish motive in his work. His labour is one of love, and his ambition, for the time at least, is bounded by the desire to *do something* for science. And from a multitude of such enthusiasts the great professors come. Great mountains are only found in mountainous countries.

I find myself insensibly led to speak of the encouragement of research in this country, and, although it has been very largely discussed in scientific circles, I will venture to add a few words. To promote original work here, I believe it is indispensable that our professors should be well paid. It would save them from the necessity of supplementing their incomes by commercial analyses, and thus enable them to devote their spare time to original work. And to secure that they shall have spare time, I would like to see in every laboratory a competent assistant, who would be able occasionally to take up the professor's lectures, should he be engaged in important work. There are many around me who know how very exacting original investigation is, and how necessary it is, at times, to be able to work on without interruption, bits and scraps of time being of no value. I am glad to see that the Oxford Commission also recommends the appointment of well-paid assistants. Well-paid professorships and well-paid assistantships would be attractive prizes for our students to work up to; and if it were clearly understood that the only way to these prizes was through original investigation, we should very soon have an army of zealous and competent workers.

The plan of appointing a staff of original workers unconnected with teaching has been proposed; but I do not approve of it. The original worker is, as a rule, the best teacher, and the rising generation of students should not be deprived of the advantage of his instruction. Moreover, as I said before, the professor may be greatly assisted by his pupils.

No doubt the Government Grant Fund does a good deal for science, but the field of its operations is, under present conditions, limited. Professors, as a rule, are so occupied with teaching that they cannot avail themselves of the fund; and of those students who might be competent and willing, very few can afford to do so. Instead of trusting to the precarious and insufficient support of the fund they must endeavour to settle themselves permanently in life.

It is much to be regretted that the universities of Oxford and Cambridge, with such splendid revenues at their disposal, should contribute so little to the advancement of physical science. I hope the day is not far distant when the Fellowships—or at least a few of them—which now go to reward young men for merely passing a good examination, shall be given *without examination* to men who shall have advanced human knowledge in any department. At present, a Fellowship of 250*l*. or 300*l*. a-year, lasting ten or twelve years, and in some cases for life, may be obtained on showing proof of a good memory—or, at most, a capacity for assimilating other men's ideas. To make discoveries—to follow out a new train of thought, and establish it by experiments specially devised to that end, has been left not only without reward, but almost without recognition, in our two principal seats of learning. Is it to be so always? The world at large, ignorant as it is, has a sounder instinct on this subject, and the man who makes the humblest addition to the stock of knowledge in the world rarely fails to receive the world's respect and honour.

The suggestions I have ventured to make could not, of course, be well carried out, unless the government take into its own hands the appointment to all scientific chairs. Of this I think I see indications. I believe that sooner or later the government will assume the supreme direction of education in this country. It has already taken primary education under its control, and quite recently, here in Ireland, intermediate education to a great extent. And does the appointment of so many university commissions not show a disposition on the part of the government to assume the direction of higher education also?

SECTION C.—GEOLOGY.

The Origin and the Succession of the Crystalline Rocks, by Prof. J. Sterry Hunt, LL.D., F.R.S.—As a preliminary to a statement of the results of many years of study of the crystalline rocks in North America, the author proceeded to consider the question of their origin, which is still a subject of debate between plutonists and neptunists. The crystalline silicate rocks naturally divide themselves into three groups, namely, those indigenous stratified formations which have been called primitive or primary, those masses to which, from their relations to contiguous rocks, geologists assign an exotic origin, and in accordance with a generally-accepted theory, have agreed to call igneous or plutonic; and a third and distinct group of rock-masses which, though like the last, clearly posterior to those encasing them, are now, by most geologists, admitted to be of aqueous origin. This third group includes metalliferous lodes and various other crystalline veinstones, and is conveniently designated endogenous. It is not always easy to distinguish between the rocks of these three groups; there are not wanting those who have assigned an igneous origin to metalliferous lodes, and many still confound endogenous granitic veins with the mineralogically similar plutonic granites. In like manner the distinction between the latter and the stratified granitoid gneisses is frequently not very apparent. That the movement of flow in extravasated plutonic rocks may give to their constituent minerals a stratiform arrangement, is a fact of which both exotic granites and doleritic dykes and masses afford illustrations. Moreover, the arrangement due to successive depositions upon the walls of a fissure may give to an endogenous mass a structure which simulates that of a sedimentary rock, and imparting to granitic veinstones a resemblance to gneiss; while a laminated structure sometimes results from the arrangement of the crystals developed in a cooling mass. Hence there are not wanting those who include under the head of plutonic rocks not only the clearly marked exotic granites, dolerites, and diorites, but the granitoid gneisses, the massive bedded greenstones, and likewise the more schistose rocks with which these gneisses and greenstones are often so intimately associated that it is difficult to separate them. According to those who hold this plutonic view, the crystalline rocks represent the igneous crust of the globe, and their frequent stratiform structure is due to agencies in great part anterior to the production of sedimentary rocks. In opposition to this view is that of the neptunist, who, starting from the fact that the elements of an aqueous sediment may, through the action of chemical and crystallogenic forces, pass into new combinations and acquire a new structure, argues not only that all indigenous crystalline rocks have had an aqueous origin, but that the exotic masses themselves represent the last stages of this process of alteration or metamorphosis of sedimentary beds.

Further inquiry into the chemical and lithological composition of the crystalline rocks, however, brings to light difficulties in the way of both of these hypotheses. To begin with the plutonist view, volcanic rocks, both ancient and modern, are more or less nearly related in composition to the gneisses and the stratified greenstones, but we seek in vain among undoubted volcanic or igneous rocks for the chemical representatives of the masses of serpentine, olivine, steatite, chlorite, quartzite, magnetite, oligist, and limestone, which appear in the primary formations, and have, all of them, by geologists of the school in question, been regarded as of igneous or plutonic origin. To account for the presence of such rocks among the more or less feldspathic aggregates—chiefly gneisses and greenstones—which make up the greater portion of the crystalline formations, three hypotheses have been imagined by plutonists. According to the first of these the earth's interior is a reservoir from which, at times, have been ejected not only basic and acidic feldspathic rocks, but molten masses of olivine, iron-oxyde, quartz, and limestone. Other geologists of this school have sought to account for the presence of some of these exceptional rocks by a process of so-called segregation, which would assimilate them to endogenous masses. The chemical and geognostical difficulties in the way of both of these hypotheses have, however, led to their general rejection for the third, which supposes these rocks to have been formed by a subsequent local alteration of portions of the ordinary plutonic rocks.

From acknowledged cases of alteration or replacement in mineral species which result in pseudomorphs, and from the more frequent cases of envelopment and of isomorphism, which have been taken for examples of pseudomorphism, it was argued that many species are capable of being changed into others by the loss or addition of certain elements, so that the resulting body often contains no portion of its original constituents. Extending this view from single crystals to rock-masses, it was maintained that different portions of an igneous or plutonic formation, whether basic or acidic, might be transformed into serpentine, chlorite, or limestone. These changes were supposed to depend on the action of water, which, aided by heat, was regarded as the efficient agent in the local alterations of plutonic rocks. At the same time the adjacent sedimentary strata were supposed to share in these changes, thus giving rise to what have been called contact-formations. In their latest form these doctrines have been well set forth by von Lasaulx and by Knop. This third hypothesis, then, proposes to account for the presence of various exceptional varieties of rock among ordinary plutonic formations by supposing that limited portions of these have, at different times, been the subject of very unlike chemical processes, resulting in their complete change into new forms of rock by what has been called pseudomorphic alteration, or metamorphosis. As, however, such a conversion involves a change not only of form but of substance, it has been more properly designated a metasomatosis.

We have next to consider the neptunean view as ordinarily expounded. This, while it accounts by sedimentation for the stratiform arrangement of the crystalline rocks and explains the existence therein of beds of iron ores and limestones, still presents many of the difficulties which are encountered in the plutonist view. If, as most neptunists maintain, the great crystalline series have been derived from the alteration of uncrystalline ones, which were not only similar to those of palæozoic and more recent times, but are, in fact, portions of these which in adjacent regions are still known to us in their original unchanged condition, how are we to explain the genesis of the feldspathic and hornblendic rocks which predominate in these crystalline formations? The sandstones and shales from which, in this view, they are supposed to be formed, could never, by themselves, give rise to the rocks in question, since they are deficient in the alkalis, and to a greater or less extent in the other bases required for the production of the constituent silicates. To explain their origin, therefore, it becomes necessary to admit the introduction of these various bases from without, and to suppose a series of metasomatic processes more wonderful than those imagined by the plutonist. The latter, by his hypothesis, has already at hand feldspathic and hornblendic rocks which are to be the subjects of metasomatosis, while the neptunist has only the products of their decay.

In either hypothesis, we have to account for the presence, in the primary formations, of beds and interstratified masses of a great number of exceptional silicated rocks very distinct in composition from any mechanically-formed sediments, including not only silicates like serpentine, olivine, steatite, chlorite, pinite, garnet, epidote, and hornblende, but of pure orthoclase, as well as of triclinic feldspars. Each of these species would require, for its production from any ordinary igneous or aqueous rock, a separate and independent metasomatic process—involving the addition of certain elements and the abstraction of others—until the whole heterogeneous crystalline series was complete. The author illustrated these views by examples from recent writers, and concluded that the hypothesis of metasomatosis, as maintained both by plutonists and neptunists, supposes the operation in solid rocks of processes of circulation, absorption, elimination, selection, and aggregation scarcely to be equalled in the economy of highly-organised beings, and not easily imagined in the masses of the mineral kingdom.

Certain geologists suppose the existence of two classes of crystalline stratified rocks: the one neptunean, and consisting

of altered portions of palæozoic or more recent sediments, and the other—more ancient—which may be either neptunean or plutonic in origin. The history of geology gives many examples of crystalline formations which have been, in turn, assigned to various geological horizons from the cainozoic to the base of the palæozoic, but have since been found to belong to a pre-palæozoic period. In the opinion of the author we have no good and sufficient reason for believing in the present existence of any uncrystalline representative of these crystalline formations, or of any such formation which is not pre-Silurian, if not pre-Cambrian, in age. There are, however, many examples of local alterations of later sediments by hydro-thermal action, which has developed in these many crystalline minerals identical with those found in the more ancient rocks. The advocates of the neptunean hypothesis have, for the most part, sought for the origin of the crystalline rocks in sediments of a later date, of which the uncrystalline representatives are still to be found. There are, however, reasons for believing that in eozoic, or pre-Cambrian times, there prevailed chemical activities, dependent upon greater subterranean temperature, different atmospheric conditions, and abundance of thermal waters, and that under these circumstances were deposited the materials for the crystalline rocks. There have not been wanting those who have sought in similar hypothetical conditions for the origin of these rocks. De la Beche, in 1834, imagined them to be chemical deposits, due to the action of the heated ocean upon the earth's primeval crust before the dawn of life.

The author's researches into the composition and structure of the crystalline rocks, conjoined with his studies of the chemistry of natural waters, led him, in 1860, to reject the hitherto received view of the epigenic or metasomatic origin of serpentine, steatite, chlorite, and similar rocks, and to maintain their derivation from silicates formed by chemical processes and deposited in the water of lakes or seas. This view he soon after extended to the various other exceptional rocks found in crystalline formations, which it was in 1864 asserted, had been "formed by a crystalline and molecular re-arrangement of silicates generated by chemical processes in waters at the earth's surface." In elucidation of this view the author referred to the insoluble silicates now separated in the evaporation of many natural waters, to the formation from the earliest times to the present of deposits of serpentine, sepiolite, glauconite, and of aluminous silicates allied to chlorite, which are found either forming beds or filling the cavities of various marine organic forms from the foraminifers of to-day to the crinoids of palæozoic time, and the eozoon of the Laurentian. The formation in modern times of crystalline zeolites and quartz in thermal waters was also cited in illustration of this view of the generation of various mineral silicates by causes now in operation, which, it is believed, were far more active in eozoic times. This was not, as had been already suggested by others, a process confined to a seething primeval ocean before the advent of life, but was continued through long ages under varying chemical conditions, and was contemporaneous with the deposition of successive strata of limestone and detrital matters. The argillaceous portions of these, it is conceived, may have taken part in the reactions with thermal waters.

We have thus, in the opinion of the author, a reasonable mode of accounting for the origin of the various rocks of the crystalline formation, and a consistent and complete neptunean theory, which does not invoke the aid of metasomatosis. It has, since it was proposed eighteen years ago, met with the approval of many whose studies have made them the fittest judges of its reasonableness. Among those who have either formally given their adhesion to it, or have enunciated similar views, may be mentioned the names of Delesse, Renard, Gümbel, Credner, Alphonse Favre, and Gastaldi.

The chemical activities concerned in the production of the various silicates have doubtless suffered gradual change and diminution through the successive ages of eozoic time, from which have resulted mineralogical and lithological differences in the crystalline terranes. Each of these includes quartzites and limestones, in which latter certain silicates, such as serpentine, hornblende, and micas, are occasionally found. It is in those aluminiferous rocks, which are without lime or magnesia, that are seen the essential and characteristic differences dependent, as long ago pointed out by the author, upon a decrease in the proportion of alkalis. As we pass from the older to the younger of the eozoic terranes, the feldspar, orthoclase, and albite, become partially or wholly replaced by silicates like muscovite, damonite, and paragonite, and finally by andalusite, fibrolite, cyanite, and pyrophyllite.

The author alluded briefly to the changes by which the ancient aqueous deposits were transformed into crystalline stratified rocks by what Gümbel has designated diagenesis, as distinguished from their supposed origin by epigenesis or metasomatic change. The question of the relation of the indigenous crystalline rocks to the endogenous and exotic masses included in them was noticed, the author alluding to the hypothesis, which he has elsewhere maintained, that the source of all exotic or eruptive rocks is to be found in the displacement or extravasation of ancient deposits of neptunean origin.

Coming to the second division of his subject, the author asserted that the study of the crystalline rocks of North America shows the existence of several distinct groups or terraces.

The Laurentian, which is the most ancient, includes in its lower part a mass of unknown thickness of granitoid gneiss, often hornblendic (Ottawa gneiss), succeeded—perhaps unconformably—by what has been called the Grenville series, consisting of similar gneisses and hornblendic rocks with intercalated quartzites and iron ores. These two divisions make up together the lower Laurentian of Logan, of which the thickness in Canada may greatly exceed 20,000 feet.

The Norian, which is the upper Laurentian or Labradorian of Logan, rests unconformably upon the Laurentian, and is remarkable for a great development of rocks composed chiefly of labradorite or related plagioclase feldspars, which have been called labradorite-rock or norite. The interstratified gneisses, quartzites, and limestones of the Norian are not unlike those of the Laurentian. This series, which abounds in great beds of titanic iron-ore, has a great volume which may exceed the thickness of 10,000 feet assigned to it by Logan.

The Laurentian is in many parts unconformably overlaid by the Huronian series, which is characterised by a great development of greenstones, generally hornblendic, with epidote, chlorite, steatite, serpentine, and soft hydrous mica-schists, often called talcose, besides argillites, quartzites, and limestones, generally magnesian. It abounds in metalliferous deposits, including magnetic and specular iron-ores, chrome, and sulphurets of copper, iron, and nickel, and has had assigned to it in different regions a thickness of from ten to twenty thousand feet.

In many parts of North America there exists a great development of rocks characterised by the predominance of orthofelsite or petrosilex, often becoming a quartziferous porphyry. This, which is apparently the *hälleflinta* of Sweden, was regarded as eruptive until, in 1869, the author showed it to be a stratified series with some associated quartzites and schists, and then included it in the lower part of the Huronian. Hitchcock, who has since studied these rocks in New Hampshire, has called them lower Huronian. From their absence in many localities at the base of the typical Huronian, it is conjectured that they may belong to a more ancient and distinct series.

The Montalban or White Mountain series is characterised by micaceous gneisses, generally called granites, which pass into quartzose and feldspathic mica-schists, often abounding in garnet, staurolite, fibrolite, and cyanite. Great masses of dark green gneissoid hornblendic rock, very distinct from the Huronian greenstones, abound in the Montalban, which also includes beds of a peculiar olivine rock, besides quartzites and crystalline limestones. This series abounds in endogenous granitic veins, containing muscovite, beryl, tourmaline, apatite, and oxide of tin. It probably equals the Huronian in thickness, and is supposed to overlie it.

The Taconian series includes a great volume of characteristic mica-schists, often quartzose, but seldom distinctly feldspathic, and frequently consisting in large part of damonite, or of pyrophyllite. Some of these, like the schists of the Montalban, include garnet and chiastolite. They are associated with quartzites and with dolomites and limestones, all of which are also frequently micaceous. Associated with these are found serpentines and granular hornblendic rocks of a peculiar type, very unlike those of the preceding groups and much less crystalline. The quartzites are in large part detrital rocks. This series, which yields the statuary marbles of North America, has a thickness of about 5,000 feet and is the lower Taconic of Emmons. It is found reposing alike on the Laurentian, Huronian, and Montalban, and is overlaid, in apparent unconformity, by the upper Taconic, which is identical with the Quebec group of Logan. This, which consists of many thousand feet of sandstones and argillites, with some limestones, includes

among its strata organic forms belonging to various divisions of the Cambrian up to the Arenig. The Taconian, although containing an undescribed linguloid shell and a so-called scolithus, is by the author considered provisionally as distinct from the Cambrian. It has yielded in Ontario, besides scolithus, the Eozoon Canadense, and may perhaps be regarded as the connecting link between the eozoic and palæozoic ages.

The upper Taconic, or so-called Quebec group in Eastern North America, is separated by a stratigraphical break from the succeeding portion of the Cambrian, the Bala group (Trenton, Utica, and Loraine), while, on the contrary, the supposed discordance in the regions just mentioned at the summit of the latter, corresponding to the division between Cambrian and Silurian in Wales, appears to have been based on a misconception. There is, however, an important palæontological break at this horizon, connected with a great deposit of barren detrital rocks, which marked the close of the Cambrian period, and the author records his opinion that the name of lower Silurian, as well as that of Siluro-Cambrian, which he, with others, has applied to the Bala or upper division of the Cambrian is to be rejected as being historically incorrect and as tending to perpetuate false views of the palæontological relations between these and the succeeding rocks.

The early advocates in North America of the metamorphism of palæozoic rocks taught, in the first place, the stratigraphical equivalence of the upper Taconic (or lower and middle Cambrian) with the upper Cambrian, and further maintained that these rocks had suffered various degrees and various kinds of metamorphism, as the result of which they had assumed, in different areas, the characters of the Taconian, the Montalban, and Huronian, and the Laurentian; the lithological differences between these several series being regarded as marks of the greater or less alteration which, it was supposed, these uncrystalline Cambrian sediments had undergone. Other geologists have imagined portions of these same crystalline formations in North America to be altered strata of Silurian, Devonian, and even of triassic age.

The great groups of eozoic rocks already described constitute, however, in the author's opinion, as many great stratified series which, before the Cambrian time, existed in their present crystalline condition, and had been successively subjected to the accidents of uplift, contortion, and denudation, so that the newer eozoic groups were, at the beginning of the paleozoic period, distributed irregularly over the floor of fundamental Laurentian gneiss. These various crystalline groups are found, with a singular persistence and uniformity of lithological character, from Alabama to Newfoundland, along the Atlantic belt, and thence westward through Canada to the great lakes, and beyond, in the vast regions of the Cordilleras to the Pacific slope.

The author had some years since pointed out the remarkable similarity between these various crystalline groups of North America and the crystalline rocks of the British Islands, and had lately been able, by new observations, to confirm his conclusions. Among the crystalline formations of Donegal he had indicated representatives of Laurentian, Montalban, and Huronian, and the latter he had recently observed largely developed in Argyleshire and Perthshire. To the Huronian also he refers the green schists of Anglesea and Carnarvonshire, in both of which regions the orthofelsite or hälleflinta series at the base of the Huronian (the so-called porphyries), and likewise the more ancient gneisses, are well represented. He would, however, leave this subject to his friend Dr. Henry Hicks, who has so happily mastered the obscure problems of the pre-Cambrian geology of Wales. The studies of Gastaldi and others enable us to assert that similar series of ancient rocks occur in the same order in the Alps; and we infer that the chemical and physical conditions which presided over the production of the crystalline stratified rocks were world-wide.

SECTION D.

BIOLOGY.

Department of Anatomy and Physiology.

ADDRESS BY R. MCDONNELL, M.D., F.R.S., VICE-PRESIDENT OF THE SECTION.

SINCE this Association met twelve months ago the science of physiology has suffered an irreparable loss. In February last Claude Bernard died in the sixty-fifth year of his age. He was interred with a degree of pomp never in this country, and rarely even in France, accorded to men of science. His country showed how justly and how highly they estimated the merit of a man who, gentle, unobtrusive, modest, by the greatness of his genius and the brilliancy of his many discoveries shed a lustre on the land which gave him birth. It was my privilege to have been at one time a pupil of this illustrious physiologist. It will be my pride if I can show to a thoughtful and cultivated audience, such as I have now the honour to address, that the discoveries of my honoured master, although of necessity made by experiment on animals, have added much to that stock of knowledge which has conferred the greatest benefits upon mankind. In an address like this—limited to a short time—it would not be possible to give a detailed account of the work accomplished by Bernard. To do so would be to give a history of the progress of physiology for the last thirty-five years. His researches were so extended, and some of his discoveries so vast, that by comparison they seem to make others appear small, as the gigantic Californian pine seems to dwarf a goodly-sized oak which grows alongside it. Hence, we speak of Bernard's less important researches—of his minor discoveries, although of sufficient magnitude to have seemed great if made by another. Of these I cannot speak at length, yet some of my hearers will know that the services which Bernard has rendered to science by his researches on the pneumogastric nerves, the fifth pair, the chorda tympani, the facial, &c., are not small. Assuredly, the same may be said for his observations on "recurrent sensibility;" on the blood pressure and the gases of the blood; on the variations of colour of this fluid, according to the active or passive condition of the functions of the organ traversed by it; on the variations of temperature during these conditions of functional activity or inactivity; on the elective elimination by the glands of substances introduced into the economy, or of those which, as morbid products, accumulate in the system as the result of certain morbid states; on the special character and action of the varieties of the salivary secretions; upon the influence of the nervous centres on the secretion of saliva; on the electric phenomena manifested in nerve and muscle; on albuminuria connected with lesions of the nervous system; and (notably in its important practical bearings on uræmia) on the modifications of the secretions of the stomach and intestines after arrest of the elimination of urea through the natural channels. Claude Bernard, in truth, left his mark deeply on every aspect of physiology on which he touched. His discoveries, however, as regards the functions of the pancreas, of the liver, and concerning the vaso-motor system of nerves, are those on which his fame will ever chiefly rest.

Dr. McDonnell then dwelt in detail on the importance of Bernard's researches from a medical point of view.

Department of Anthropology.

The business of this department was opened by the following address from Prof. Huxley.

When I undertook, with the greatest possible pleasure, to act as a lieutenant of my friend the president of this Section, I steadfastly purposed to confine myself to the modest and useful duties of that position. For reasons, with which it is not worth while to trouble you, I did not propose to follow the custom which has grown up in the Association of delivering an address upon the occasion of taking the chair of a section or department. In clear memory of the admirable addresses which you have had the privilege of hearing from Prof. Flower, and just now from Dr. M'Donnell, I cannot doubt that that practice is a very good one; but I would venture to say, to use a term of philosophy, that it looks very much better from an objective than from a subjective point of view. But I found that my resolution, like a great many good resolutions that I have made in the course of my life, came to very little, and that it was thought desirable that I should address you in some way. But I must beg of you to understand that this is no formal address. I have simply announced it as a few introductory remarks, and I must ask you to forgive whatever of crudity and imperfection there may be in the mode of expression of what I have to say, although naturally I shall do my best to take care that there is neither crudity nor inaccuracy in the substance of it. It has occurred to me that I might address myself to a point in connection with the business of this department which forces itself more or less upon the attention of everybody, and which, unless the bellicose instincts of human nature are less marked on this side of St. George's Channel than on the other, may possibly have something to do with the large audiences we are always accustomed to see in the anthropological

department. In the Geological Section I have no doubt it will be pointed out to you, or, at any rate, such knowledge may crop up incidentally, that there are on the earth's surface what are called *loci* of disturbance, where, for long ages, cataclysms and outbursts of lava and the like take place. Then everything subsides into quietude; but a similar disturbance is set up elsewhere. In Antrim, at the middle of the tertiary epoch, there was such a great centre of physical disturbance. We all know that at the present time the earth's crust, at any rate, is quiet in Antrim, while the great centres of local disturbance are in Sicily, in Southern Italy, in the Andes, and elsewhere. My experience of the British Association does not extend quite over a geological epoch, but it does go back rather longer than I care to think about; and when I first knew the British Association, the *locus* of disturbance in it was the Geological Section. All sorts of terrible things about the antiquity of the earth, and I know not what else, were being said there, which gave rise to terrible apprehensions. The whole world, it was thought, was coming to an end, just as I have no doubt that, if there were any human inhabitants of Antrim in the middle of the tertiary epoch, when those great lava streams burst out, they would not have had the smallest question that the whole universe was going to pieces. Well, the universe has not gone to pieces. Antrim is, geologically speaking, a very quiet place now, as well cultivated a place as one need see, and yielding abundance of excellent produce; and so, if we turn to the Geological Section, nothing can be milder than the proceedings of that admirable body. All the difficulties that they seemed to have encountered at first have died away, and statements that were the horrible paradoxes of that generation are now the commonplaces of schoolboys. At present the *locus* of disturbance is to be found in the Biological Section, and more particularly in the anthropological department of that Section. History repeats itself, and precisely the same terrible apprehensions which were expressed by the aborigines of the Geological Section, in long far back time, is at present expressed by those who attend our deliberations. The world is coming to an end, the basis of morality is being shaken, and I don't know what is not to happen if certain conclusions which appear probable are to be verified. Well, now, whoever may be here thirty years hence—I certainly cannot—but, depend upon it, whoever may be speaking at the meeting of this department of the British Association thirty years hence will find, exactly as the members of the Geological Section have found, on looking back thirty years, that the very paradoxes and conclusions, and other horrible things that are now thought to be going to shake the foundations of the world will by that time have become parts of every-day knowledge and will be taught in our schools as accepted truth, and nobody will be one whit the worse.

The considerations which I think it desirable to put before you in order to show the foundations of the conclusions at which I have very confidently arrived, are of two kinds. The first is a reason based entirely upon philosophical considerations, namely, this—that the region of pure physical science, and the region of those questions which specially interest ordinary humanity, are apart, and that the conclusions reached in the one have no direct effect in the other. If you acquaint yourself with the history of philosophy, and with the endless variations of human opinion therein recorded, you will find that there is not a single one of those speculative difficulties which at the present time torment many minds as being the direct product of scientific thought, which is not as old as the times of Greek philosophy, and which did not then exist as strongly and as clearly as they do now, though they arose out of arguments based upon merely philosophical ideas. Whoever admits these two things—as everybody who looks about him must do—whoever takes into account the existence of evil in this world and the law of causation—has before him all the difficulties that can be raised by any form of scientific speculation. And these two difficulties have been occupying the minds of men ever since man began to think. The other consideration I have to put before you is that, whatever may be the results at which physical science as applied to man shall arrive, those results are inevitable—I mean that they arise out of the necessary progress of scientific thought as applied to man. You all, I hope, had the opportunity of hearing the excellent address which was given by our president yesterday, in which he traced out the marvellous progress of our knowledge of the higher animals which has been effected since the time of Linnæus. It is no exaggeration to say that at this present time the merest tyro knows a thousand times as much on the subject as is contained in the work of Linnæus, which was then the standard authority. Now how has that been brought about? If you consider what zoology, or the study of animals, signifies, you will see that it means an endeavour to ascertain all that can be studied, all the answers that can be given respecting any animal under four possible points of view. The first of these embraces considerations of structure. An animal has a certain structure, a certain mode of development, which means a series of stages in that structure. In the second place, every animal exhibits a great number of active powers, the knowledge of which constitutes its physiology; and under those active powers we have, as physiologists, not only to include such matters as have been referred to by Dr. M'Donnell in his observations, but to take into account other kinds of activity. I see it announced that the Zoological Section of to-day is to have a highly interesting paper by Sir John Lubbock on the habits of ants. Ants have a polity, and exhibit a certain amount of intelligence, and all these matters are proper subjects for the study of the zoologist as far as he deals with the ant. There is yet a third point of view in which you may regard every animal. It has a distribution. Not only is it to be found somewhere on the earth's surface, but palæontology tells us, if we go back in time, that the great majority of animals have had a past history—that they occurred in epochs of the world's history far removed from the present. And when we have acquired all that knowledge which we may enumerate under the heads of anatomy, physiology, and distribution, there remains still the problem of problems to the zoologist, which is the study of the causes of those phenomena, in order that we may know how those things came about. All these different forms of knowledge and inquiry are legitimate subjects for science, there being no subject which is an illegitimate subject for scientific inquiry, except such as involves a contradiction in terms, or is itself absurd. Indeed, I don't know that I ought to go quite so far as this at present, for, undoubtedly, there are many benighted persons who have been in the habit of calling by no less hard names conceptions which our president tells us must be regarded with much respect. If we have four dimensions of space we may have forty dimensions, and that would be a long way beyond that which is conceivable by ordinary powers of imagination. I should, therefore, not like to draw too closely the limits as to what may be contradiction to the best established principles. Now, let us turn to a proposition which no one can possibly deny—namely, that there is a distinct sense in which man is an animal. There is not the smallest doubt of that proposition. If anybody entertains a misgiving on that point he has simply to walk through the museum close by in order to see that man has a structure and a framework which may be compared, point for point and bone for bone, with those of the lower animals. There is not the smallest doubt moreover that, as to the manner of his becoming, man is developed, step by step, in exactly the same way as they are. There is not the smallest doubt that his activities—not only his mere bodily functions, but his other functions—are just as much the subjects of scientific study as are those of ants or bees. What we call the phenomena of intelligence, for example (as to what else there may be in them, the anthropologist makes no assertion)—are phenomena following a definite causal order just as capable of scientific examination, and of being reduced to definite law, as are all those phenomena which we call physical. And just as ants form a polity and a social state, and just as these are the proper and legitimate study of the zoologist, so far as he deals with ants, so do men organise themselves into a social state, and though the province of politics is of course outside that of anthropology, yet the consideration of man, so far as his instincts lead him to construct a social economy, is a legitimate and proper part of anthropology, precisely in the same way as the study of the social state of ants is a legitimate object of zoology. So with regard to other and more subtle phenomena. It has often been disputed whether in animals there is any trace of the religious sentiment. That is a legitimate subject of dispute and of inquiry; and if it were possible for my friend Sir John Lubbock to point out to you that ants manifest such sentiments he would have made a very great and interesting discovery, and no one could doubt that the ascertainment of such a fact was completely within the province of zoology. Anthropology has nothing to do with the truth or falsehood of religion—it holds itself absolutely and entirely aloof from such questions—but the natural history of religion, and the origin and the

growth of the religions entertained by the different kinds of the human race are within its proper and legitimate province. I now go a step farther, and pass to the distribution of man. Here, of course, the anthropologist is in his special region. He endeavours to ascertain how various modifications of the human stock are arranged upon the earth's surface. He looks back to the past, and inquires how far the remains of man can be traced. It is just as legitimate to ascertain how far the human race goes back in time as it is to ascertain how far the horse goes back in time; the kind of evidence that is good in the one case is good in the other; and the conclusions that are forced on us in the one case are forced on us in the other also. Finally, we come to the question of the causes of all these phenomena, which, if permissible in the case of other animals, is permissible in the animal man. Whatever evidence, whatever chain of reasoning justifies us in concluding that the horse, for example, has come into existence in a certain fashion in time, the same evidence and the same canons of logic justify us to precisely the same extent in drawing the same kind of conclusions with regard to man. And it is the business of the anthropologist to be as severe in his criticism of those matters in respect to the origin of man as it is the business of the palæontologist to be strict in regard to the origin of the horse; but for the scientific man there is neither more nor less reason for dealing critically with the one case than with the other. Whatever evidence is satisfactory in one case is satisfactory in the other; and if any one should travel outside the lines of scientific evidence, and endeavour either to support or oppose conclusions which are based upon distinctly scientific truths, by considerations which are not in any way based upon scientific logic or scientific truth—whether that mode of advocacy was in favour of a given position, or whether it was against it, I, occupying the chair of the Section, should, most undoubtedly, feel myself called upon to call him to order, and to tell him that he was introducing considerations with which we had no concern whatever.

I have occupied your attention for a considerable time; yet there is still one other point respecting which I should like to say a few words, because some very striking reflections arose out of it. The British Association met in Dublin twenty-one years ago, and I have taken the pains to look up what was done in regard of our subject at that period. At that time there was no anthropological department. That study had not yet differentiated itself from zoology, or anatomy, or physiology, so as to claim for itself a distinct place. Moreover, without reverting needlessly to the remarks which I placed before you some time ago, it was a very volcanic subject, and people rather liked to leave it alone. It was not until a long time subsequently that the present organisations of this Section of the Association was brought about; but it is a curious fact, that although proper anthropological subjects were at the time brought before the Geographical Section—with the proper subject of which they had nothing whatever to do—I find that even then more than half of the papers that were brought before that section were, more or less distinctly, of an anthropological cast. It is very curious to observe what that cast was. We had systems of language—we had descriptions of savage races—we had the great question, as it then was thought, of the unity or multiplicity of the human species. These were just touched upon, but there was not an allusion in the whole of the proceedings of the Association at that time to those questions which are now to be regarded as the burning questions of anthropology. The whole tendency in the present direction was given by the publication of a single book, and that not a very large one—namely, "The Origin of Species." It was only subsequent to the publication of the ideas contained in that book that one of the most powerful instruments for the advance of anthropological knowledge—namely, the Anthropological Society of Paris—was founded. Afterwards the Anthropological Institute of this country, and the great Anthropological Society of Berlin came into existence, until it may be said that now there is not a branch of science which is represented by a larger or more active body of workers than the science of anthropology. But the whole of these workers are engaged, more or less intentionally, in providing the data for attacking the ultimate great problem, whether the ideas which Darwin has put forward in regard to the animal world are capable of being applied in the same sense and to the same extent to man. That question, I need not say, is not answered.

It is a vast and difficult question, and one for which a complete answer may possibly be looked for in the next century; but the method of inquiry is understood; and the mode in which the materials are now being accumulated bearing on that inquiry, the processes by which results are now obtained, and the observation of these phenomena leads to the belief that the problem also, some day or other, will be solved. In what sense I cannot tell you. I have my own notion about it, but the question for the future is the attainment, by scientific processes and methods, of the solution of that question. If you ask me what has been done within the last twenty-one years towards this object, or rather towards clearing the ground in the direction of obtaining a solution, I don't know that I could lay my hand upon much of a very definite character—except as to methods of investigation—save in regard to one point. I have some reason to know that about the year 1860, at any rate, there was nothing more volcanic, more shocking, more subversive of everything right and proper, than to put forward the proposition that as far as physical organisation is concerned there is less difference between man and the highest apes than there is between the highest apes and the lowest. Now my memory carries me back sufficiently to remind me that, in 1860, that question was not a pleasant one to touch on. The other day I was reading a recently-published valuable and interesting work, "L'Espèce Humaine," by a very eminent man, M. de Quatrefages. He is a gentleman who has made these questions his special study, and has written a great deal and very well about them. He has always maintained a temperate and fair position, and has been the opponent of evolutionary ideas, so that I turned with some interest to his work as giving me a record of what I could look on as the progress of opinion during the last twenty years. If he has any bias at all it is one in the opposite direction to which my own studies would lead me. I cannot quote his words, for I have not the book with me, but the substance of them is that the proposition which I have just put before you is one, the truth of which no rational person acquainted with the facts could dispute. Such is the difference which twenty years has made in that respect, and speaking in the presence of a great number of anatomists, who are quite able to decide a question of this kind, I believe that the opinion of M. de Quatrefages on the subject is one they will all be prepared to indorse. Well, it is a comfort to have got that much out of the way. The second direction in which I think great progress has been made is with respect to the processes of anthropometry, in other words, in the modes of obtaining those data which are necessary for anthropologists to reason upon. Like all other persons who have to deal with physical science, we confine ourselves to matters which can be ascertained with precision, and nothing is more remarkable than the exactness which has been introduced into the mode of ascertaining the physical qualities of man within the last twenty-five years. One cannot mention the name of Broca without the greatest gratitude; and I am quite sure that when Prof. Flower brings forward his paper on cranial measurements on Monday next you will be surprised to see what precision of method and what accuracy are now introduced, compared with what existed twenty-five years ago, into these methods of determining the physical data of man's structure. If, further, we turn to those physiological matters bearing on anthropology which have been the subject of inquiry within the last score of years, we find that there has been a vast amount of progress. I would refer you to the very remarkable collection of the data of sociology by Mr. Herbert Spencer, which contains a mass of information useful on one side or the other, in getting towards the truth. Then I would refer you to the highly interesting contributions which have been made by Prof. Max Müller and by Mr. Tylor to the natural history of religions, which is one of the most interesting chapters of anthropology. In regard to another very important topic, the development of art and the use of tools and weapons, most remarkable contributions have been made by General Lane Fox, whose museum at Bethnal Green is one of the most extraordinary exemplifications that I know of the ingenuity, and, at the same time, of the stupidity of the human race. Their ingenuity appears in their invention of a given pattern or form of weapon, and their profound stupidity in this, that having done so, they kept in the old grooves, and were thus prevented from getting beyond the primitive type of these objects and of their ornamentation. One of the most singular things in that museum is its exemplification—the wonderful tendency of the human mind when once it has got into a groove to stick there. The great object of scientific investigation is to run counter to that tendency.

Lastly, great progress has been made in the last twenty years in the direction of the discovery of the indications of man in a fossil state. My memory goes back to the time when anybody who broached the notion of the existence of fossil man would have been simply laughed at. It was held to be a canon of palæontology that man could not exist in a fossil state. I don't know why, but it was so; and that fixed idea acted so strongly on men's minds that they shut their eyes to the plainest possible evidence. Within the last twenty years we have an astonishing accumulation of evidence of the existence of man in ages antecedent to those of which we have any historical record. What the actual date of those times was, and what their relation is to our known historical epochs, I don't think anybody is in a position to say. But it is beyond all question that man, and not only man, but what is more to the purpose, intelligent man, existed at times when the whole physical conformation of the country was totally different from that which characterises it now. Whether the evidence we now possess justifies us in going back further, or not—that we can get back as far as the epoch of the drift is, I think, beyond any rational question or doubt; that may be regarded as something settled—but when it comes to a question as to the evidence of tracing back man further than that—and recollect drift is only the scum of the earth's surface—I must confess that to my mind the evidence is of a very dubious character.

Finally, we come to the very interesting question—as to whether, with such evidence of the existence of man in those times as we have before us, it is possible to trace in that brief history any evidence of the gradual modification from a human type somewhat different from that which now exists to that which is met with at present. I must confess that my opinion remains exactly what it was some eighteen years ago when I published a little book which I was very sorry to hear my friend, Prof. Flower, allude to yesterday, because I had hoped that it would have been forgotten amongst the greater scandals of subsequent times. I did there put forward the opinion that what is known as the Neanderthal skull is, of human remains, that which presents the most marked and definite characteristics of a lower type—using the language in the same sense as we would use it in other branches of zoology. I believe it to belong to the lowest form of human being of which we have any knowledge, and we know from the remains accompanying that human being, that as far as all fundamental points of structure were concerned, he was as much a man—could wear boots just as easily—as any of us, so that I think the question remains pretty much where it was. I don't know that there is any reason for doubting that the men who existed at that day were in all essential respects similar to the men who exist now. But I must point out to you that this conviction is by no means inconsistent with the doctrine of evolution. The horse, which existed at that time, was in all essential respects identical with the horse which exists now. But we happen to know that going back further in time the horse presents us with a series of modifications by which it can be traced back from an earlier type. Therefore it must be deemed possible that man is in the same position, although the facts we have before us with respect to him tell in neither one way nor the other. I have now nothing more to do than to thank you for the great kindness and attention with which you have listened to these informal remarks.

SECTION E.

GEOGRAPHY.

Opening Address by the President, Prof. Sir C. Wyville Thomson, F.R.S.

In doing me the honour to select me to preside over this section on the present occasion, the Council of the British Association have doubtless had in view the part which it has been my privilege to take in contributing to the physical description of the earth, as director of the civilian scientific staff on board H.M.S. *Challenger*. I will not, therefore, apologise for following the example of several of my more immediate predecessors in leaving to others the subject of topographical geography which I have never made a special study, and directing your attention for the short time at my disposal to advances which have been made of late years in certain directions in the application of the physical and natural sciences to the illustration of the general condition of the earth.

Before doing so, however, I must refer to the great geographical event of the year which has passed since the geographical section of the British Association last met—the return of the African explorer, Henry Moreland Stanley. As the graphic account which Mr. Stanley has given of his journey "through the dark continent" is in all our hands, and as we may hope to have an opportunity during this meeting of hearing something further of his adventures from the great traveller himself, it will not be necessary for me at present to enter into any details either with regard to the course taken by his expedition or to the brilliant results which it has achieved. It is, however, incumbent upon us in this place to acknowledge once more the flood of light which Stanley has thrown upon the geography of Central Africa, and to express our wondering admiration of the iron will and the daring intrepidity which carried him through these long years of labour and difficulty and danger. Although, in reading Stanley's narrative, we may be forced to regret some of the dark scenes by which his terrible march was chequered, still no one who has not himself had some dealings with savages can fully understand how entirely the action of a leader, solely responsible for the lives of his party, must be guided in every emergency by considerations which he alone is in a position to weigh.

During the last few years a factor, so altered in its proportions that it has appeared almost new, has entered into the calculations of the naval executive departments of all the maritime powers; and in harmony with the rapid advance of natural knowledge and the widening recognition of its practical value, many opportunities, hitherto too often lost, have been taken advantage of. Latterly almost all special expeditions, whether despatched avowedly with the object of extending the boundaries of science, or for hydrographic purposes, or for training naval cadets, or for drilling the inmates of a penitentiary, or pioneering commercial enterprise, as in the case of Capt. Wiggins' late excursions to the mouth of the Yenisei, have been supplied more or less fully with the means of scientific observation, and have been in many cases accompanied by observers trained in one department or another of physical research.

I will simply name among many such equipped and instructed expeditions of these later days, the splendid circumnavigating voyage of the Austrian frigate *Novara*, under the command of Admiral von Wüllerstorf-Urbair. The report of the scientific results of this expedition has been published by the Austrian Government in eighteen beautifully illustrated volumes, and the completion of this work, after seventeen years of heavy labour, was one of the scientific events of the year 1877. The voyage of the Italian corvette *Magenta* round the world, so well chronicled by Prof. Enrico Hillyer Giglioli; the very important sounding voyages of Capt. Belknap, in the American surveying ship *Tuscarora;* the *Hassler* expedition, the last crowning effort with which the elder Agassiz closed a long and brilliant career devoted to the study and illustration of nature, and the many scientific explorations undertaken from year to year by the officers of the American coast survey, with the co-operation of the younger Agassiz and Count Pourtales; the tentative cruises of the British gunboats *Lightning* and *Porcupine*, culminating in the *Challenger* expedition; the scientific voyage round the world of the German frigate *Gazelle;* the several expeditions sent out by different powers to observe the transit of Venus; the German Arctic expedition, under Capt. Koldewey; the several Swedish expeditions, so rich in zoological results, to the Spitzbergen Sea, under the guidance of Otto Torell, Nordenskjöld, and others; the exhaustive researches into the conditions physical and biological of the North Sea, by the North Sea Commission, under the direction of Dr. H. A. Meyer; the voyage of the *Tegethoff*, which Lieut. Payer has rendered ever memorable by his thrilling story of disaster, success, and heroism; the Arctic voyage of the *Alert* and the *Discovery*, of which Sir George Nares has just published the semi-official narrative, a simple and charming account of almost superhuman effort and insuperable obstruction, which it is impossible to read without a feeling of regret that the devoted little band had attempted what was so hopeless, and at the same time a conviction that if their task had been practicable by human skill and bravery, it must certainly have been accomplished. But although this expedition of necessity failed in its main object, that of reaching the Pole, the additional information which we gain from Capt. Nares' volume and from the more popular sketch of the voyage by Capt. Markham on the physical condition of the Arctic Sea is in the highest degree

valuable. I must also mention the very important cruises in connection with the Norwegian Department of Fisheries, which, through the skilled labours of Prof. Mohn and Prof. G. O. Sars, annually contribute largely to our knowledge of the distribution of temperature, of the course of the ocean currents, and of the range of animal life in the North Atlantic. I observe in a letter from Prof. Mohn, dated from Hammerfest on the 10th of last month, that the expedition of the past year has had a successful cruise to Bear Island, where she has left letters for the Dutch Arctic schooner the *Willem Barentz*, and has made many important temperature observations. Prof. Mohn speaks highly of the service rendered by Negretti and Zambra's new reversing thermometer. This is a most ingenious instrument, so constructed that by a simple mechanical arrangement the temperature may be registered at any given depth, irrespective of any number of zones of temperature, higher or lower, through which the instrument may have passed in descending. In the *Challenger* we felt greatly the want of such a thermometer, for although generally throughout the ocean the temperature of the water falls steadily from a surface maximum to a minimum at the bottom, in the Arctic and Antarctic Seas—where a special interest attaches to the vertical distribution of temperatures—the coldest layer is frequently, as in Prof. Mohn's observations, on the surface; and a warmer belt intervenes between it and a bottom-stratum, probably in many cases of intermediate temperature. With the ordinary deep-sea registering thermometer the temperature of the lowest layer cannot be ascertained with certainty. We had Negretti and Zambra's earlier instrument on the reversing principle on board during the latter part of our cruise, but through some defect in construction we did not find its indications trustworthy for great depths. I always believed the plan of construction of this instrument to be good, and I am very glad to find from Prof. Mohn's report that this defect has now been entirely overcome.

It follows from the nature of these many and varied enterprises that the department of geographical science to whose progress they have most specially contributed is the physical geography of the sea; and the special appliances with which they have been provided have been principally instruments for determining the temperature of the water at different depths, the depth of the sea and the nature of the sea-bottom, and, in some few cases, the distribution of the deep-sea fauna. It is of course impossible for me in so short a time even to sketch their several lines of investigation, or to attempt to assign to each its share in the general advance of knowledge; I think it may be better that I should give an outline of some of the conditions of the regions to which they refer by the light of their combined results. I am aware that in taking this course I shall be forced to face questions on which there has been some controversy; and I can only say that I will avoid the controversial aspects of such questions as far as possible, and merely describe as shortly as I can the condition of things as they appear to me.

The General Ocean Circulation.—It was pointed out long ago by Sir Charles Lyell that many of the most marked phenomena of the present physical condition of the globe depend upon the fact that the surface of the world is divided into two hemispheres, one of which contains nearly the whole of the dry land of this world, while the other is almost entirely covered by water. The centre of the land hemisphere is somewhere in Great Britain, and the centre of the water hemisphere, which includes the southern sea, the South Pacific, whatever antarctic land there may be, Australia, and the southern point of South America, is in this neighbourhood of New Zealand. With a full knowledge of the absolute continuity of the ocean we have hitherto been too much in the habit of regarding it as composed of several oceans, each possibly under special physical conditions. All recent observations have, however, shown us that the vast expanse of water which has its centre in the southern hemisphere is the one great ocean of the world, of which the Atlantic with the Arctic Sea and the North Pacific are merely northward extending gulfs; and that any physical phenomena affecting obviously one portion of its area must be regarded as one of an interdependent system of phenomena affecting the ocean as a whole.

Shallow as the stratum of water forming the ocean is—a mere film in proportion to the radius of the earth—it is very definitely split up into two layers, which, so far as all questions concerning ocean movements and the distribution of temperature is concerned, are under very different conditions. At a depth varying in different parts of the world, but averaging perhaps 500 fathoms, we arrive at a layer of water at a temperature of 40° F., and this may be regarded as a kind of neutral band separating the two layers. Above this band the temperature varies greatly over different areas, the isothermobathic lines sometimes tolerably equally distributed, and at other times crowding together towards the surface, while beneath it the temperature almost universally sinks very slowly and with increasing slowness to a minimum at the bottom.

The causes of natural phenomena, such as the movements of great masses of water, or the existence over large areas of abnormal temperature conditions, are always more or less complex, but in almost all cases one cause appears to be so very much the most efficient that in taking a general view all others may be practically disregarded; and speaking in this sense it may be said that the trade-winds and their modifications and counter-currents are the cause of all movements in the stratum of the ocean above the neutral layer. This system of horizontal circulation, although so enormously important in its influences upon the distribution of climate is sufficiently simple. Disregarding minor details, the great equatorial current driven from east to west across the northerly extensions of the ocean by the trade-winds, impinges upon the eastern coasts of the continents. A branch turns northwards and circles round the closed end of the Pacific, tending to curl back to the North American coast from its excess of initial velocity; and in the Atlantic, following a corresponding course, the Gulf Stream bathes the shores of Northern Europe, and a branch of it forces its way into the Arctic basin, and battling against the palæocrystic ice, keeps imperfectly open the water-way by which Nordenskjöld hopes to work his course to Behring's Strait. The southern deflections are practically lost, being to a great extent, though not entirely dissipated in the great westerly current of the southern anti-trades.

One of the most singular results of these later investigations is the establishment of the fact that all the vast mass of water, often upwards of 2,000 fathoms in thickness, below the neutral band, is moving slowly to the northward; that in fact the depths of the Atlantic, the Pacific, and the Indian Oceans are occupied by tongues of the Antarctic Sea, preserving in the main its characteristic temperatures. The maintenance of a low temperature while the temperature of the floor of the ocean must be higher, and that of the upper layers of the sea greatly higher, is in itself a conclusive proof of steady movement of the water from a cold source; and the fact that the temperature of the lower layers of water, both in the Atlantic and the Pacific, is slightly but perceptibly raised to the northward, while the continuity of every layer with a corresponding layer in the southern sea can be clearly traced, indicates the southern position of that source.

The immediate explanation of this very unexpected phenomenon seems simple. For some cause or other, as yet not fully understood, evaporation is greatly in excess of precipitation over the northern portion of the land-hemisphere, while over the water-hemisphere, and particularly over its southern portion, the reverse is the case; thus one part of the general circulation of the ocean is carried on through the atmosphere, the water being raised in vapour in the northern hemisphere, hurried by upper wind currents to the zone of low barometric pressure in the south, where it is precipitated in the form of snow or rain, and welling thence northwards in the deepest channels on account of the high specific gravity dependent on its low temperature, it supplies the place of the water which has been removed.

The cold water wells northwards, but it meets with some obstructions on its way, and these obstructions, while they prove the northward movement, if further proof was needed, bring out another law by which the distribution of ocean temperature is regulated. The deeper water sinks slowly to a minimum at the bottom, so that if we suppose the temperature at a depth of 2,000 fathoms to be 36° F., the temperature at a depth of 3,000 may be, say, 32°. Now, if in this case the slow current meet on its northward path a continuous barrier in the form of a submarine mountain ridge rising to within 2,000 fathoms of the sea-surface, it is clear that all the water below a temperature of 36° will be arrested, and, however deep the basin beyond the ridge may be, the water will maintain a minimum of 36° from a depth of 2,000 fathoms to the bottom. In many parts of the ocean we have most remarkable examples of the effect upon deep-sea temperature of such barriers intersecting cold in-draughts, the most marked instance, perhaps, a singular chain of

closed seas at different temperatures among the islands of the Malay Archipelago; but we have also a striking instance nearer home. Evaporation is greatly in excess of precipitation over the area of the Mediterranean, and consequently, in order to keep up the supply of water to the Mediterranean, there is a constant inward current through the Straits of Gibraltar from the Atlantic; I need not at present refer to an occasional tidal counter-current. The minimum temperature of the Mediterranean is about 54° F. from a depth of 100 fathoms to the bottom. The temperature of 54° is reached in the Atlantic at the mouth of the Straits of Gibraltar at a depth of about 100 fathoms, so that in all probability future soundings will show that the free water-way through the Straits does not greatly exceed 100 fathoms in depth.

The Depth of the Sea, and the Nature of Modern Deposits.—It seems now to be thoroughly established by lines of trustworthy soundings which have been run in all directions, that the average depth of the ocean is a little over 2,000 fathoms, and that in all probability it nowhere exceeds 5,000 fathoms. Depths beyond 4,000 fathoms are rare and very local, and seem to be usually pits in the neighbourhood of volcanic islands. In all the ocean basins there are depressions extending over considerable areas where the depth reaches 3,000 fathoms or a little more, and these depressions maintain a certain parallelism with the axes of the neighbouring continents.

Within 300 or 400 miles of the shore, whether in deep or in shallow water, formations are being laid down, whose materials are derived mainly from the disintegration of shore rocks, and which consequently depend for their structure and composition upon the nature and composition of the rocks which supply their materials. These deposits imbed the hard parts of the animals living on their area of deposition, and they correspond in every way with sedimentary formations with which we are familiar, of every age. In water of medium depths down to about 2,000 fathoms, we have in most seas a deposit of the now well-known globigerina-ooze, formed almost entirely of the shells of foraminifera living on the sea-surface, and which after death have sunk to the bottom. This formation, which occupies a large part of the bed of the Atlantic and a considerable part of that of the Pacific and Southern Seas, is very like chalk in most respects, although we are now satisfied that it is being laid down as a rule in deeper water than the chalk of the cretaceous period.

In depths beyond 2,500 or 3,000 fathoms no such accumulations are taking place. The shores of continents are usually too distant to supply land detritus, and although the chalk-building foraminifera are as abundant on the surface as they are elsewhere, not a shell reaches the bottom; the carbonate of lime is entirely dissolved by the carbonic acid contained in the water during the long descent of the shells from the surface. It therefore becomes a matter of very great interest to determine what processes are going on, and what kind of formations are being laid down in these abyssal regions, which must at present occupy an area of not less than ten millions of square miles.

The tube of the sounding instrument comes up from such abysses filled with an extremely fine reddish clay, in great part amorphous, but containing, when examined under the microscope, a quantity of distinctly recognisable particles, organic and inorganic. The organic particles are chiefly siliceous, and for the most part the shells or spines of radiolarians which are living abundantly on the surface of the sea, and apparently in more or less abundance at all depths. The inorganic particles are minute flakes of disintegrated pumice, and small crystalline fragments of volcanic minerals; the amorphous residue is probably principally due to the decomposition of volcanic products, and partly to the ultimate inorganic residue of decomposed organisms. There is ample evidence that this abyssal deposit is taking place with extreme slowness. Over its whole area, and more particularly in the deep water of the Pacific, the dredge or trawl brings up in large numbers nodules very irregular in shape, consisting chiefly of peroxide of iron and peroxide of manganese, deposited in concentric layers in a matrix of clay, round a nucleus formed of a shark's tooth, or a piece of bone, or an otolith, or a piece of siliceous sponge, or more frequently a fragment of pumice. These nodules are evidently formed in the clay, and the formation of the larger ones and the segregation of their material must have taken a very long time. Many of the sharks' teeth to which I have alluded as forming the nuclei of the nodules, and which are frequently brought up uncoated with foreign matter, belong to species which we have every reason to believe to be extinct. Some teeth of a species of *Carcharodon* are of enormous size, four inches across the base, and are scarcely distinguishable from the huge teeth from the tertiary beds of Malta. It is evident that these semi-fossil teeth, from their being caught up in numbers by the loaded line of the trawl, are covered by only a very thin layer of clay.

Another element in the red clay has caused great speculation and interest. If a magnet be drawn through a quantity of the fine clay well diffused in water, it will be found to have caught on its surface some very minute magnetic spherules, some apparently of metallic iron in a passive state, and some of metallic nickel. From the appearance of these particles, and from the circumstance that such magnetic dust has been already detected in the sediment of snow-water, my colleague Mr. Murray has a very strong opinion that they are of cosmic origin—excessively minute meteorites. They certainly resemble very closely the fine granules which frequently roughen the surface of the characteristic skin of meteorites, and from their composition and the circumstances under which they are found there is much to be said in favour of this view. I cannot, however, hold it entirely proved; there can be little doubt, from the universal presence of water-logged and partially decomposed pumice on the bottom, and from the constant occurrence of particles of volcanic minerals in the clay, that the red clay is formed in a great measure by the decomposition of the lighter products of submarine volcanoes drifted about by currents, and finally becoming saturated with water and sinking; and it is well known that both iron and nickel in a metallic state are frequently present in minute quantities in igneous rocks. I think it is conceivable that the metallic spherules may be derived from this source.

So far as we can judge, after a most careful comparative examination, the deposit which is at present being formed at extreme depths in the ocean does not correspond either in structure or in chemical composition with any known geological formation; and, moreover, we are inclined to believe, from a consideration of their structure and of their imbedded organic remains, that none of the older formations were laid down at nearly so great depths—that, in fact, none of these have anything of an abyssal character. These late researches tend to show that during past geological changes abyssal beds have never been exposed, and it seems highly probable that until comparatively recent geological periods such beds have not been formed.

It appears now to be a very generally received opinion among geologists—an opinion which was first brought into prominence by Prof. Dana—that the "massive" eruptions which originated the mountain chains which form the skeleton of our present continents, and the depressions occupied by our present seas date from the secular cooling and contraction of the crust of the earth from a period much more remote than the deposition of the earliest of the fossiliferous rocks, and that during the period chronicled by the successive sedimentary systems, with many minor oscillations by which limited areas have been alternately elevated and depressed, the broad result has been the growth by successive steps of the original mountain chains and the extension of the continents by their denudation, and the corresponding deepening of the original grooves. If this view be correct—and it certainly appears to me that the reasoning in its favour is very cogent—it is quite possible that until comparatively recent times no part of the ocean was sufficiently deep for the formation of a characteristic abyssal deposit.

Time will not allow me even to allude to the interesting results which have been obtained from the determination of the density of sea water from different localities and different depths, and from the analysis of sea water and its contained gases, and perhaps these results have been scarcely sufficiently worked out as yet to afford safe bases for generalisation. I must, however, say a few words as to certain additions which have been made to our knowledge of the two hitherto impregnable strongholds of the frost, the regions round the North and South Poles.

The Arctic Regions.—The question which has of late held the most prominent place in all discussions about the conditions of the Arctic Regions, particularly since the voyage of Dr. Hayes, is whether it is possible that there can be at all times or at any time anything in the form of an open Polar sea. This question seems now to be virtually settled, and in the most unsatisfactory manner imaginable. There can be no doubt that in the year 1871 Count Wilczek, in the schooner *Isbjörn*, found the sea between Novaya Zemlya and Spitzbergen nearly free from ice, and that the same sea presented to Weyprecht and Payer in the following year a dangerous stretch of moving and impenetrable

pack. There can be no doubt that in the year 1861 Dr. Hayes gazed over an expanse of open water where, in 1875-76, Capt. Nares studied the conditions of palæocrystic ice. It is evident, therefore, that the Polar basin, or at all events such portions of it as have been hitherto reached, is neither open sea nor continuous ice, but a fatal compromise between the two, an enormously heavy pack formed by the piling up and crushing together of the floe of successive years, in frequent movement, breaking up and shifting according to the prevailing direction of the wind, and leaving open, now here and now there, lanes and vistas of deceptive open water which may be at any moment closed and converted into a chaotic mass of hurtling floe-bergs by a hurricane from another direction. It seems, however, that in certain seasons there is more open water in the direction of Grinnell's Land and Smith's Sound than in others, and that there are also years comparatively favourable for the northward route following the lead of Franz-Josef Land; and there seem now to be only two plans, one nearly as hopeless as the other, to choose between in any future attempt—either to establish several permanent Polar stations, as proposed by Lieut. Weyprecht, and already initiated at one point, so far as preliminaries are concerned, by Capt. Tyson and Capt. Howgate, and to seize the opportunity of running north in early autumn from the station where the sea appears most open, or to run as far north as possible at enormous expense, with a great force of men and abundance of provisions and paraffin oil, and push northwards during the arctic winter by a chain of communicating stations with ice-built refuge huts. It seems possible that in a cold season, with the pack in the condition in which Markham found it in 1876, some progress might be made in this way if it were conceivable that the end to be gained was worth the expenditure of so much labour and treasure.

The Antarctic Regions.—But little progress has been made during the last quarter of a century in the actual investigation of the conditions of that vast region which lies within the parallel of 70° S. Some additional knowledge has been acquired, and the light which recent inquiries have thrown upon the general plan of ocean circulation and the physical properties of ice, have given a new direction to what must partake for some time to come of the nature of speculation.

From information derived from all sources up to the present time, it may be gathered that the unpenetrated area of about 4,700,000 square miles surrounding the South Pole is by no means certainly a continuous "Antarctic Continent," but that it consists much more probably partly of comparatively low continental land, and partly of a congeries of continental (not oceanic) islands, bridged between and combined, and covered to the depth of about 1,400 feet, by a continuous ice-cap; with here and there somewhat elevated continental chains, such as the groups of land between 55° and 95° W., including Peter the Great Island and Alexander Land, discovered by Billingshausen in 1821, Graham Land and Adelaide Island, discovered by Biscol in 1832, and Louis Philippe Land by D'Urville in 1838, and at least one majestic modern volcanic range discovered by Ross in 1841 and 1842, stretching from Balleny Island to a latitude of 78° S., and rising to a height of 15,000 feet. It seems, so far as is at present known, that the whole of the antarctic land, low and high, as well as the ice-cap of which a portion of the continuous continent may consist, is bordered to some distance by a fringe of ice, which is bounded to seaward by a perpendicular ice-cliff, averaging 230 feet in height above the sea-level. Outside the cliff a *floe*, which attains near the barrier a thickness of about 20 feet, and in some places by piling a considerably greater thickness, extends northwards in winter to a distance varying according to its position with reference to the southward trending branches of the equatorial current; and this floe is replaced in summer by a heavy drifting pack with scattered ice-bergs. Navigating the Antarctic Sea in the southern summer, the only season when such navigation is possible, it has been the opinion of almost all explorers, that after forcing a passage through an outer belt of heavy pack and ice-bergs, moving as a rule to the north-westward, and thus fanning out from the ice-cliff in obedience to the prevailing south-easterly winds, a band of comparatively clear water is to be found within.

Several considerations appear to me to be in favour of the view that the area round the South Pole is broken up and not continuous land. For example, if we look at a general ice-chart we find that the sea is comparatively free from icebergs, and that the deepest notches occur in the "Antarctic Continent" at three points, each a little to the eastward of south of one of the great land masses. Opposite each of these notches a branch of the equatorial current is deflected southwards by the land, and is almost merged in the great drift-current which sweeps round the world in the Southern Sea before the westerly anti-trades. But while the greater portion of the Brazilian current, the East Australian current, and the southern part of the Agulhas current are thus merged, they are not entirely lost; for at these points of junction with the drift-current of the westerlies, the isobathytherms are slightly deflected to the southwards, and it is opposite these points of junction that we have comparatively open sea and penetrable notches in the southern pack. But we have not only the presumed *effect* of this transfer of warmer water to the southwards; we were able to detect its presence in the *Challenger* by the thermometer. Referring to the result of a serial temperature sounding on February 14, 1874, with a surface temperature of 29° F. at a depth of from 300 to 400 fathoms, there is a band of water at a temperature of more than half a degree above the freezing-point. That this comparatively warm water is coming from the north there is ample proof. We traced its continuity with a band at the same depth gradually increasing in warmth to the northward, and it is evident that its heat can be derived from no other source, and that it must be continually receiving new supplies, for it is overlaid by a band of colder water, tending to mix with it by convection.

It is, of course, possible that these warm currents may by coincidence be directed towards those notches already existing in a continental mass of land; but such a coincidence would be remarkable, and there is certainly a suggestion of the alternative that the "continent" may consist to so great an extent of ice as to be liable to have its outline affected by warm currents.

In high southern latitudes it seems that all the icebergs are originally tabular, the surface perfectly level and parallel with the surface of the sea, a cliff about 230 feet high bounding the berg. The top is covered with a layer of the whitest snow; now and then a small flock of petrels take up their quarters upon it, and trample and soil some few square yards, but after their departure one of the frequent snow showers restores it in a few minutes to its virgin whiteness. The upper part of the cliff is pale blue, which gradually deepens towards the base. When looked at closely the face of the cliff is seen to be traversed by a delicate ruling of faint blue lines, the lines being more distant from one another above and becoming gradually closer. The distance between the well-marked lines near the top of a berg may be of a foot or even more, while near the surface of the water it is not more than two or three inches, and the space between the blue lines have lost their dead whiteness and have become hyaline or bluish. The blue lines are very unequal in their strength and in their depth of colouring; sometimes a group of very dark lines gives a marked character to a part of a berg. Between the stronger blue lines near the top of the cliff a system of closer lines may be observed, marking the division of the ice by still finer planes of lamination; but in the narrower spaces near the water-line they are blended and lost. The blue lines are the sections of sheets of clear ice; the white intervening bands are the sections of layers of ice where the particles are not in such close contact—ice probably containing some air.

The stratification in all these icebergs is, I believe, originally horizontal and conformable, or very nearly so. In many, while melting and beating about in the sea, the strata become inclined at various angles, or vertical or even reversed; in many they are traversed by faults, or twisted, or contorted, or displaced; but I believe that all deviations from a horizontal arrangement are due to changes taking place in the icebergs themselves.

I think there can be no doubt, from their shape and form, and their remarkable uniformity of character, that these great table-topped icebergs are prismatic blocks riven from the edge of the great antarctic ice-sheet. I conclude, therefore, that the upper part of the iceberg, including by far the greater part of its bulk, and culminating in the portion exposed above the surface of the sea, was formed by the piling up of successive layers of snow during the period, amounting perhaps to centuries, during which the ice-cap was slowly forcing its way over the low land, and out to sea over a long extent of gentle slope, until it reached a depth considerably beyond 200 fathoms, when the lower specific weight of the ice caused an upward strain which at length overcame the cohesion of the mass, and portions were rent off and floated away. The icebergs when they are first dispersed float in from 200 to 250 fathoms; when, therefore, they have been

drifted to latitudes of 65° or 64° south, the bottom of the berg, the surface which forced itself glacier-like over the land, just reaches the layer at which the temperature of the water distinctly rises; and is rapidly melted, and the pebbles and land *débris* with which it is more or less charged are precipitated. That this precipitation takes place all over the area where the icebergs are breaking up, constantly and to a considerable extent, is evident from the fact that the matter brought up by the sounding instrument and the dredge is almost entirely composed of such deposits from ice; for diatoms, foraminifera, and radiolarians are present on the surface in large numbers, and unless the deposit from the ice were abundant it would soon be covered and masked by the skeletons of surface organisms.

The curious question now arises, what is the cause of the uniform height of the southern icebergs—that is to say, what is the cause of the restriction of the thickness of the free edge of the ice-cap to 1,400 fathoms? I have mentioned the gradual diminution in thickness of the strata of ice in a berg from above downwards. The regularity of this diminution leaves it almost without a doubt that the layers observed are in the same category, and that therefore the diminution is due to subsequent pressure or other action upon a series of beds, which were at the time of their deposition nearly equally thick. About 60 or 80 feet from the top of an iceberg, the strata of ice a foot or so in thickness, although of a white colour and thus indicating that they contain a considerable quantity of air, are very hard, and the specific weight of the ice is not much lower than that of layers three inches thick nearer the water-line of the berg. The upper layers have been manifestly produced by falls of snow after the berg has been detached.

Now it seems to me that the reduction in thickness cannot be due to compression alone, but that a portion of the substance of the lower layers must have been removed. It is not easy to see why the temperature of the earth's crust, under a widely extended and practically permanent ice-sheet of great thickness, should ever fall below the freezing-point; and it is a matter of observation that at all seasons of the year vast rivers of muddy water flow into the frozen sea from beneath the great glaciers which are the issues of the ice-sheet of Greenland. Ice is a very bad conductor, so that the cold of winter cannot penetrate to any great depth into the mass. The normal temperature of the surface of the earth's crust, at any point where it is uninfluenced by cyclical changes, is at all events above the freezing-point, so that the temperature of the floor of the ice-sheet would certainly have no tendency and fall below that of the stream passing over it. The pressure upon the deeper beds of the ice must be enormous at the bottom of an ice-sheet 1,400 feet in thickness—not much less than a quarter of a ton on the square inch. It seems, therefore, probable that under the pressure to which the body of ice is subjected a constant system of melting and regelation is taking place, the water passing down by gravitation from layer to layer until it reaches the floor of the ice-sheet, and finally working out channels for itself between the ice and the land, whether the latter be subærial or submerged.

I should think it probable that this process, or some modification of it may be the provision by which the indefinite accumulation of ice over the antarctic continent is prevented and a certain uniformity in the thickness of the ice-sheet maintained—that in fact ice at the temperature at which it is in contact with the surface of the earth's crust within the antarctic regions cannot support a column of itself more than 1,400 feet high without melting. It is suggested to me by Prof. Tait that the thickness of the ice-sheet very probably depends upon its area, as the amount of melting through squeezing and the earth's internal heat, will depend upon the facility of the escape of the water. The problem is, however, an exceedingly complex one, and we have perhaps scarcely sufficient data for working it out.

The Fauna of the Deep Sea.—I can scarcely regret that it is utterly impossible for me on this occasion to enter into any details with regard to the relations of the abyssal fauna, the department of the subject which has naturally had for me the greatest interest. Recent investigations have shown that there is no depth limit to the distribution of any group of gill-bearing marine animals. Fishes, which, from their structure and from what we know of the habits of their congeners, must certainly live on the bottom, have come up from all depths, and at all depths the whole of the marine invertebrate classes are more or less fully represented. The abyssal fauna is of a somewhat special character, differing from the fauna of shallower water in the relative proportions in which the different invertebrate types are represented. It is very uniform over an enormously extended area, and in this respect it fully confirms the anticipations of the great Scandinavian naturalist Lovén, communicated to this Association in the year 1844. It is a rich fauna, including many special genera and an enormous number of special species, of which we, of course, know as yet only a fraction; but I do not think I am going too far in saying that from the results of the *Challenger* expedition alone the number of known species in certain classes will be doubled. The relations of the abyssal fauna to the faunæ of the older tertiary and the newer mesozoic periods are much closer than are those of the faunæ of shallow water; I must admit, however, that these relations are not so close as I expected them to be—that hitherto we have found living only a very few representatives of groups which had been supposed to be extinct. I feel, however, that until the zoological results of several of these later voyages, and especially those of the *Challenger*, shall have been fully worked out, it would be premature to commit myself to any generalisations.

I have thus attempted to give a brief outline of certain defensible general conclusions, based upon the results of recent research. Some years ago, certain commercial enterprises, involving the laying of telegraph cables over the bed of the sea, proved that the extreme depths of the ocean were not inaccessible. This somewhat unexpected experience soon resulted in many attempts, on the part of those interested in the extension of the boundaries of knowledge, to use what machinery they then possessed to determine the condition of the hitherto unknown region. This first step was naturally followed by a development of all appliances and methods bearing upon the special line of research; and within the last decade the advance of knowledge of all matters bearing upon the physical geography of the sea has been confusingly rapid—so much so, that at this moment the accumulation of new material has far outstripped the power of combining and digesting and methodising it. This difficulty is greatly increased by the extreme complexity of the questions, both physical and geological, which have arisen. Steady progress is, however, being made in both directions, and I trust that in a few years our ideas as to the condition of the depth of the sea may be as definite as they are with regard to regions to which we have long had ready access.

SECTION G.

MECHANICAL SCIENCE.

OPENING ADDRESS BY THE PRESIDENT, EDWARD EASTON, C.E.

On the Conservancy of Rivers and Streams.

By the conservancy of rivers and streams I mean the treatment and regulation of all the water that falls on these islands from its first arrival in the shape of rain and dew to its final disappearance in the ocean.

I had at first, in my ignorance, contemplated treating the subject in a still wider manner by referring to the rivers and streams of other countries; but I soon found that the vast extent of the field to be traversed would make it extremely unlikely that I could, with any satisfactory result, attempt the more restricted task which I have now before me.

The question of the conservancy of rivers and streams involves the consideration of their regulation for the following principal purposes:—

1st. For the supply of pure and wholesome water for the domestic and sanitary wants of the population.

2nd. For the supply of water of proper quality and sufficient quantity for industrial purposes.

3rd. For the proper development of water power.

4th. For the drainage and irrigation of land.

5th. For navigation and commerce.

6th. For the preservation of fish.

Until the appointment last year of the Select Committee presided over by the Duke of Richmond, no attempt, as far as I am aware, has been made to grapple with the question as a whole, and the Report made by them omitted to deal with, at least, two of the objects I have indicated as being necessary to the proper dealing with the subject.

The recommendations made in the Report of that Committee were most important, and will, if carried out, remove many of the difficulties which stand in the way of a complete system of conservancy of our rivers.

So much has been written on the engineering details of this subject, by men far better qualified than I am to deal with them, that I shall confine myself to the simple statement of the principles which have been recognised by the chief authorities as essential, and to a few suggestions, which my own experience leads me to think may be of some value. Almost all the great engineers of former generations, who have paid attention to this question, Smeaton, Telford, Rennie, Golborne, Mylne, Walker, Rendel, Stephenson, Jessop, Chapman, Beardmore, and without mentioning names, many of the most eminent now living, have agreed to the following general propositions:—

That the freer the admission of the tidal water, the better adapted is the river for all purposes, whether of navigation, drainage, or fisheries.

That its sectional area and inclination should be made to suit the required carrying power of the river through its entire length, both for the ordinary flow of the water, and for floods.

That the downward flow of the upland water should be equalised as much as possible throughout the entire year; and

That all abnormal contaminations should be removed from the streams.

In carrying out these principles, it is perhaps superfluous to say, that modifications must be introduced to suit the particular phenomena of each river. In some watershed areas it would be easy to construct reservoirs, which would to a great extent equalize the flow and reduce floods. In others, it might be better to control the floods by means of embankments. In others, to have weirs, and sluices, delivering into side channels, parallel to the main stream, with the same object. Sometimes reservoirs, or receptacles, must be made for catching the *débris* brought down by the streams. In fact, every river must be treated as a separate entity. It is therefore necessary that a systematic collection of data relating to rainfall, the geological character of the gathering ground, and the volume of each separate stream, should be made for each watershed area; and this should be carried on for a sufficient length of time to enable a fairly correct estimate to be formed of the behaviour of the river both in time of flood and in time of drought. The establishment of self-acting, tide-registering gauges at several points of every outfall should be insisted on. By these means the whole of the phenomena of a watershed area could be ascertained and recorded, and safe and trustworthy knowledge could be obtained, which would contribute towards the determination, not only of the works which ought to be executed, but of the incidence of the taxation by which the necessary funds should be raised. For instance, it is obvious that where the geological character of a watershed is variable, one portion of it consisting of a permeable stratum, such as chalk or red sandstone, and another portion of an impervious stratum, such as the tertiary clays or the shales of the millstone grit, the same works would not be adapted to each section of the river, nor would it be fair to charge all with the expense according to the same scale of contribution. The former, that is the permeable stratum, is not only, from its absorbent nature, not the cause of floods, but is, by reason of that characteristic, absolutely constituted by nature one of the very works which must be devised by art to mitigate the effects of rainfall on the latter, or impervious stratum.

Bearing this in mind, I have often thought that nature might be usefully imitated in this operation, by passing the surplus rainfall into the permeable strata of the earth by means of wells, or shafts, sunk through the impermeable strata overlying them. This has been done in isolated cases for the drainage of lands, but not for the deliberate purpose of preventing floods and equalizing the flow of rivers.

I also wish to remark that artificial compensating reservoirs may be much more frequently made use of than is generally supposed to be possible, when it is considered that, so long as the dams are constructed in situations where there is no danger of their giving way, it is by no means necessary that they should be watertight, and that, therefore, they can be constructed at a very much smaller outlay. In fact, the purpose would be answered by a series of open weirs, which would collect the water in times of flood and discharge it gradually down the stream.

The example of our French neighbours in the more general use they make of movable weirs—*barrages*—of various constructions could, I am satisfied, be followed by us with very great advantage in many cases.

The question of water power is one which I think deserves more consideration than it has lately received. It has been the fashion to consider that small watermills are of little or no value, and, in the present state of most rivers and streams, this is to a very great extent true, but only because the supply of water to work them is so variable and uncertain. Sufficient attention has never yet been given to the subject of the amount of compensation water which should be given for the use of riparian proprietors when the watershed areas are dealt with for purposes of water supply. There is a kind of empirical rule acknowledged by most of the eminent water engineers, that one-third of the average flow of three consecutive dry years is a fair equivalent for the abstraction of the water falling on a gathering ground. I am strongly of opinion that, looking to imperial interests, advantage should be taken of every opportunity of dealing with a gathering ground to provide for a much larger proportion of its available water being sent down the streams, so that the natural water power of the country may be properly developed. The extra cost of the necessary works must, as a matter of course, be borne rateably by the interests benefited. It is certain that with the progress of invention many more ways of utilising this power will be discovered. At present, through the medium of compressed air, of hydraulic pressure, and of electro-motors, the great disadvantage of its being only available at the spot where the water runs is overcome, and the power can be transmitted to any distance, and used wherever it may be most conveniently applied.

Sir Robert Kane, in his most valuable and exhaustive work on the "Industrial Resources of Ireland," has given an estimate of the value of the power allowed to escape every year in the shape of floods, and the same calculation might be applied to the sister kingdom. It is probably no exaggeration to say that where running streams exist the power required for estate purposes, on the majority of properties in the United Kingdom, might be obtained by a proper conservation of the natural water resources of those streams.

The consideration I have been able to give to this subject has helped to convince me that, although a vast amount of labour and research has been devoted to it, it is nevertheless one in which "a more systematic direction to scientific inquiry" is urgently needed.

A vast collection of scientific facts exists, but they require arrangement and collation, and future observations should be more strictly classified, so that the bearing of each one, both on the others and on the subject at large, may be properly appreciated with a view to a practical result.

In France this is being done to a very large extent, and an excellent map showing the phenomena of the rivers and streams of that country is now in course of preparation. For many years also very accurate observations of the phenomena of the whole of the basin of the Seine have been taken, and have been centralised (*centralisées*) by that eminent engineer, whose loss all who had the privilege of knowing him, either in his work or in private intercourse, are deploring, M. Belgrand, late Inspector-General of the Ponts et Chaussées, and by his able coadjutor, M. M. G. Lemoine. These observations have been published in the form of diagrams, admirable in their simplicity of design, which show at a glance the bearing of every one of those phenomena on the general character of that river.

In Italy also, where there exists a distinct department having control of the hydraulic works of that country, the same exhaustive system of collation and record has been followed, and the results have been published in a series of tables. In Germany, although the same complete system is not in vogue, its chief river has been the subject of most thorough investigation, the results of which have been published in a beautiful map of the Rhine and its regulating works.

In our own country, as might be expected from the number of engineering works which have been executed, there probably exists an amount of detailed information on special and often minute points which is unsurpassed, and probably unequalled in the world.

But, although as I have said before, a great number of eminent men have treated in an exhaustive manner the phenomena relating to many of the principal rivers of Great Britain and Ireland, yet, as far as I am aware, there has been no attempt to collect and combine these most valuable, though detached fragments of knowledge, so that their relation to one another might be seen, and a general conclusion arrived at. This can only be done by the establishment of a public department analogous to those described as already existing in France and Italy.

When it is considered that many lives are annually sacrificed,

either directly by the action of floods, or by the indirect but no less fatal influence of imperfect drainage—when it is remembered that a heavy flood, such as that of last year, or that of the summer of 1875, entailed a monetary loss of several millions sterling in the three kingdoms—that during every year a quantity of water flows to waste, representing an available motive power worth certainly not less than some hundreds of thousands of pounds,—that there is a constant annual expenditure of enormous amounts for removing *débris* from navigable channels, the accumulation of which could be mainly, if not entirely prevented,—that the supply of food to our rapidly growing population, dependent, as it is at present, upon sources outside the country, would be enormously increased by an adequate protection of the fisheries,—that the same supply would be further greatly increased by the extra production of the land when increased facilities for drainage are afforded,—that, above all, the problem of our national water supply, to which public attention has of late been drawn by H.R.H. the Prince of Wales, requires for its solution investigations of the widest possible nature, I believe it will be allowed that the question, as a whole, of the management of rivers is of sufficient importance to make it worthy of being dealt with by new laws to be framed in its exclusive behalf.

I do not wish it to be understood that in suggesting the collection of additional data relating to the phenomena of rivers, I am advocating delay in dealing with the existing state of things until the facts have all been ascertained. On the contrary, I believe that the first step ought to be the establishment of a distinct Water Department, which should at once address itself to the remedying of the evils which are found to be most pressing. The time has long since arrived when the present neglected state of many of our most important streams should be dealt with, and that this was also the conviction of Parliament and of the government is evident, from the appointment of such an influential Committee as that presided over by the Duke of Richmond last session.

A new department should be created—one not only endowed with powers analagous to those of the Local Government Board, but charged with the duty of collecting and digesting for use all the facts and knowledge necessary for a due comprehension and satisfactory dealing with every river, basin, or watershed area in the United Kingdom—a department which should be presided over, if not by a Cabinet Minister, at all events by a member of the government who can be appealed to in Parliament.

The department should have entire charge of, and control over, all estuaries and navigable channels, both because these are used by foreign vessels, and therefore the responsibilities attaching to their preservation are international, and because they must be protected from hostile attack, and on these accounts are essentially imperial property. For the same reason the cost of amending and maintaining them should be defrayed out of the imperial exchequer.

As regards the regulation of the remainder of the watershed area, the conclusions arrived at in the Report of the Duke of Richmond's Select Committee seem to me entirely satisfactory. I cannot do better than give a few extracts from that Report. The Committee say—"That in order to secure uniformity and completeness of action each catchment area should, as a general rule, be placed under a single body of conservators, who should be responsible for maintaining the river from its source to its outfall in an efficient state. With regard, however, to tributary streams, the care of these might be entrusted to district committees acting under the general direction of the conservators, but near the point of junction with the principal stream they should be under the direct management of the conservators of the main channel, who should be a representative body constituted of residents and owners of property within the whole area of the watershed. The Committee go on to say that "means should be taken to ensure the appointment of a conservancy board for each watershed area," but that application should first be made by persons interested in the district, and that then the departmental authorities should send inspectors to make local inquiries and to report upon the "necessities and capacities of the district, and suggest the area and proportions of taxation."

With regard to what is probably the most important point of all, the finding of the money necessary to carry out these recommendations, the Committee advocate the introduction of a new principle of taxation, the soundness of which cannot be questioned. Instead of the principle first introduced by the statute of Henry the Eighth, and observed ever since, of levying taxes in proportion to the direct benefit conferred, the Committee propose that the rates should be distributed over the whole area of a watershed, including not only the lands, but the towns and houses and all other property situate within that area. This is in fact no more than a general application of the law of highways, which in the time of the Romans, according to Justinian, applied equally to waterways. It is perfectly just that every acre, the drainage of which contributes to the flow of the streams and rivers of every watershed area, should, in some proportion or other, contribute also to the cost of maintaining the channels of those streams and rivers in an efficient state. The incidence of the taxation must of course, as has been pointed out, be determined by the circumstances of each particular case, but there is no doubt that the conclusion of the Duke of Richmond's Committee, that "the taxation should be levied on the basis of rateable value," is the only sound, and at the same time practical, way of dealing with this difficulty.

The word "taxation" is not, I fear, generally connected with any idea of profit to the individual taxpayer. But in this case, as I hope in the course of this address I have made clear, the prevention of large present losses, and the advantages gained by an improved system, will give not only a fair but an ample return on the capital expended.

It is my firm belief that an intelligent management of watershed areas would be compatible with an absolute profit to every interest affected; that we have here no question of give and take, but that in this, as in every other case, the laws of nature, under proper and scientific regulation, can be made subservient to the needs of the highest civilisation.

THE PHONOGRAPH AND VOWEL SOUNDS[1]

III.

WE now pass to the general conclusions which may be drawn from our experiments. In the first place it seems clear that vowels do not depend on pitch alone or on the simple grouping of partial tones independently of absolute pitch. Before the constituents of a vowel can be assigned, the pitch of the prime must be named. But on the other hand the pitch of the most prominent partial of the group is not alone sufficient to allow us to name the vowel in which it appears; to do this we also require to be told the relation of the constituent partials to one another.

The sound $\bar{u}$ consists mainly of one tone generally lying in the region above *a*.

The sound $\bar{o}$ requires at least two partials; when there are only two important ones these lie in the region between *g* and f'', a region covering nearly two octaves. Indeed the upper limit may extend above f'' with a tenor or woman's voice. Other partials than the prime are reinforced by the mouth-cavity over all this region. This great range is obviously a distinguishing mark of $\bar{o}$ as compared with $\bar{u}$, perhaps *the* distinguishing mark; for when $\bar{u}$ and $\bar{o}$ are sung at various pitches, the most prominent partial, first of one letter and then of the other, is highest, and the most prominent partial of both sounds may lie on $b'\flat$, the characteristic tone of $\bar{o}$. An $\bar{u}$ sung on $b\flat$ may even have the tone $b'\flat$ more strongly present in it than an $\bar{o}$ of the same pitch. When $\bar{u}$ was sung by voice 1 on $b\flat$ the prominent partial was the second; when $\bar{o}$ was sung at the same pitch by the same voice, the second partial was still the most prominent. Thus for voice 1 the chief distinction between $\bar{u}$ and $\bar{o}$ on this note lay not in the pitch of strongest reinforcement, but in the fact that the prime was larger for $\bar{o}$ than for $\bar{u}$. When voice 5 sang $\bar{u}$ on $b\flat$ the prominent partial was the prime; when it sang $\bar{o}$ the prominent partial was the second, the prime being also strong. Thus, for voice 1, the distinction lay in the fact that the prime was much smaller for $\bar{o}$ than for $\bar{u}$. It is obvious here that the ear cannot have been guided by the absolute pitch of the reinforcement to the distinction between $\bar{o}$ and $\bar{u}$. At this pitch the distinction lies in the fact that $\bar{o}$ contains two strong partials (the prime and second), whereas $\bar{u}$ contains only one (the prime *or* the second). The argument is not weakened by saying that the $\bar{u}$ of one voice was not the same as the $\bar{u}$ of the other. Identically the same it cannot have been; nevertheless, on higher or lower notes the two voices agreed as to the composition of $\bar{u}$, and generically the vowels were certainly the

[1] Continued from p. 397.

same. There remains the fact that speakers and hearers were unconscious of any generic change in the vowel ū when the pitch of the strongly-reinforced partial changed by a whole octave.

On the other hand, it is equally clear the voice, in singing a given vowel at various pitches, does not simply produce a certain constant group of relative partial tones. Possibly, indeed, the ear might recognise a single tone, especially if very feebly accompanied by higher harmonics, as a kind of ū outside the region within which the human voice forms ū in that way. Thus Helmholtz, in his *Tonempfindungen*, says that the single tone B♭, when sounded alone, gave a very dull ū, much duller than could be produced by the voice. This tone is an octave below the place where voice I ceased to make ū by reinforcing the prime. Quite similarly it is conceivable that the group consisting of a prime and its octave might be recognised as ō even when produced below the limits within which the human voice does produce this simple harmony in singing ō. Our own impression as to the result of running the phonograph slower when it is speaking than when it is spoken to, supports this view, but we do not desire to base any inference on that. Certainly the low ō produced in this manner is not the human ō.

Moreover, we find a very decided resemblance in the relative constituents of ō at a low pitch and a° or ā at higher pitches. ō in the neighbourhood of B♭, and ā in the neighbourhood of *f* and *g*, are pretty similarly constituted. Our experiments on a° and ā are not sufficiently extended to allow any very general conclusions to be drawn, but they are sufficient to show that between certain vowels the main distinction must lie in the absolute pitch of the reinforced group of partial tones.

We are thus brought back to our original statement that in distinguishing vowels the ear is aided by two factors, one depending on the harmony or group of partials, and the other on the absolute pitch of the constituents. It seems not a little singular that the ear should attribute a distinct unity to sounds so dissimilar in their relative and absolute composition as those represented by the curves of Fig. 1.

We are forced to the conclusion already adopted by Helmholtz and Donders that the ear recognises the kind of cavity by which the reinforcement is produced; that although the sounds which issue differ so much that we fail when they are graphically represented and mathematically analysed to grasp any one prominent common feature, nevertheless by long practice the ear is able to distinguish between the different sorts of cavities which are formed in pronouncing given vowels. Something of the same kind may be observed with other sources of sound than the human voice; the resonating cavities of various musical instruments aid greatly in allowing each particular species to be recognised at once, though their effect must be widely different at different parts of the scale. It is, moreover, no mere inference that we recognise the cavity. Prof. Crum Brown's gutta percha bottle, described before, proves that we do, and that it is a group of tones reinforced by a particular kind of cavity that we call a particular vowel. But we have to consider what light the experiments throw on the kinds of cavity that are required for certain vowels. The cavities are clearly distinguished in virtue of two distinct properties: first, the pitch of their maximum resonance or strongest proper tone, and second the range of reinforcement which they are capable of producing. This latter property has, we believe, been hitherto much neglected.

Prof. Crum Brown's bottle proves that a *constant* cavity is capable of producing the constant vowel ō over a large range of pitch. On the other hand our experiments with various human voices singing ō appear to exhibit a *tuning* of the cavity by which new partials are sometimes introduced somewhat abruptly; and for the sound ū it seems certain that the cavity is tuned, that is to say, that the pitch of its proper tone is not the same when the vowel is sung on different pitches. The appreciably strong *fourth* partial in all the duplex ū's of Table VI. may here be noticed as favouring the view that in each of these examples the oral cavity had been adjusted so as to be in unison with the second partial. We may describe the ū cavity as an adjustable cavity with a very limited range of resonance, whose effect is to reinforce strongly only one partial lying above *a*. It is possible that this cavity may keep itself constant throughout the very limited range of pitch employed in ordinary speech, but when the range is increased as in singing, a certain tuning seems indispensable.

If we assume that the ō cavity is absolutely constant, we must describe it as a cavity capable of reinforcing more or less strongly tones lying anywhere between *g* and f''. This cavity

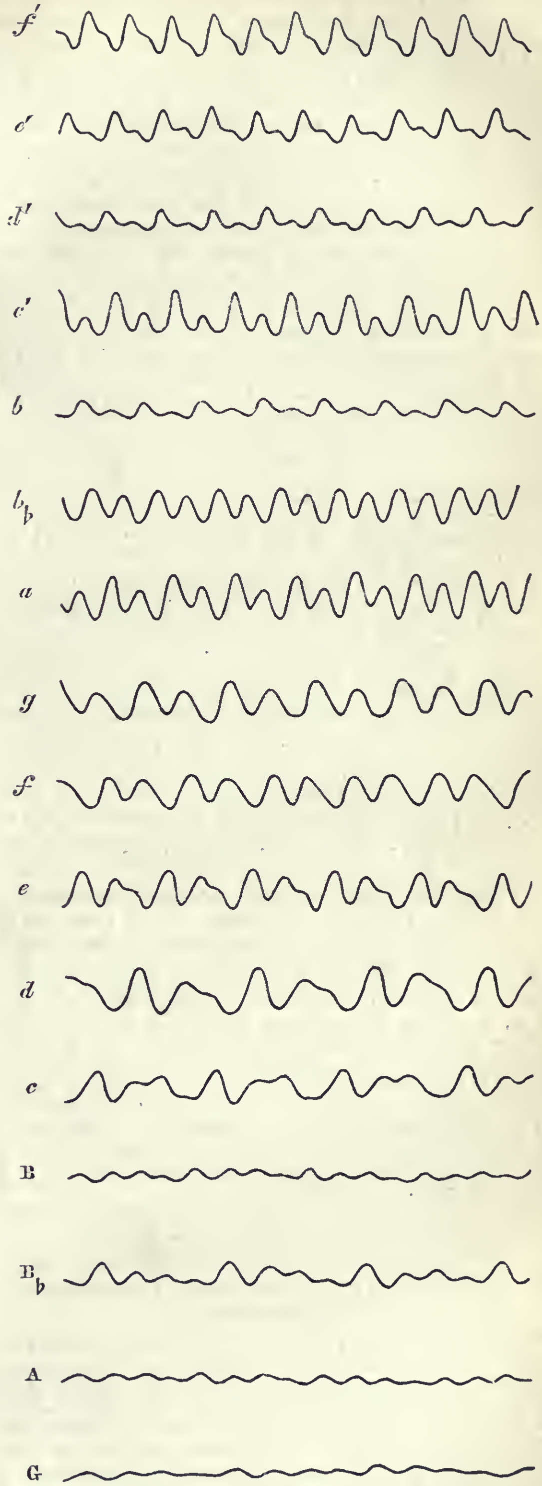

FIG. 1.[1]—*Wave-forms of ō Sung by the same Voice at Various Pitches.*

[1] We reproduce this week the figure which accompanied Profs. Jenkin and Ewing's first paper, on "The Wave-Form of Ō," p. 342. It shows the delicate forms of the curves with greater exactness, and will enable the reader to understand more clearly the value of the conclusions come to by the authors.—ED.

has, in the case of all the human voices investigated, one strong proper tone in $b'\flat$, but as the cavity which produced the artificial $\bar{o}$'s did not possess this characteristic, and it was possessed by different voices in very different degrees, it should perhaps be regarded as an accident of the human voice rather than as essential to the production of the vowel. It is difficult, however, on the constant cavity hypothesis, to see how the third partial of an $\bar{o}$ sung on or near a should not be stronger than it is. We are disposed to regard it as more probable that the $\bar{o}$ cavity also is tuned. We do not mean by this that it has a proper tone always in unison with one of the partials of the note sung, but only that there is a tendency to accommodate the pitch of the cavity so that it shall reinforce some partial more strongly than might have been the case without this tuning. On this view the range of reinforcement of each $\bar{o}$ cavity need not extend over much more than an octave, nor the range of adjustment over so much as six semitones. The upper reinforcement would lie round about $b'\flat$, on which note the greatest reinforcement can be given. Another way of putting the same conclusion would be to say that the generic character of the human $\bar{o}$ was given by the fact that the range of reinforcement of any $\bar{o}$ cavity extends over rather more than an octave, with an upper and strongest proper tone never far from $b'\flat$, but sometimes deviating slightly from that pitch on account of the voice choosing its cavity so as to bring a strong proper tone more closely into unison with one of the upper harmonics of the note sung.

We should describe the $\bar{a}$ cavity as differing from that for $\bar{o}$ chiefly in having a higher general pitch of resonance, and perhaps, also, a wider range.

It is evident that Willis and Wheatstone were right in considering that the vowel quality was given by a particular resonator, and that the pitch of maximum resonance of the resonator was an important element in determining the vowel character of the sounds produced. Willis's vowels were not thoroughly recognisable because the form and material of his resonator were not adapted to include the second element of range of reinforcement.

Further, our experiments agree with the observation of Donders that there is a pitch of maximum resonance in human mouth cavities for the vowel $\bar{o}$, although, as we have said above, we are disposed to consider the $\bar{o}$ cavity as not quite constant. We fail to distinguish any such characteristic tone in the case of $\bar{u}$, and we observe that it is fixed by Helmholtz only with considerable diffidence.

Our experiments entirely confirm Helmholtz's statement that vowel sounds are made up of harmonic partial tones, and the groups of partials, so far as he gives them, for the vowels we have investigated, agree fairly well with our results. Since these experiments were brought to a close our attention has been directed to a paper by Felix Auerbach (*Pogg. Ann. Ergänzung*, viii. 2), containing an account of experiments on vowel sounds made by him in Prof. Helmholtz's laboratory. By the aid of resonators applied to the ear he made numerical estimates of the strength of the several partial tones when vowels were sung on various notes. He was led, as we have been, to the conclusion that the relative partials were an important factor in the result as well as the absolute pitch, but we cannot say that our numbers agree with his estimates or support the deductions which he has drawn from them.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE directors of the Polytechnic are about to make an important alteration in the science department of this institution. It is intended to separate the laboratory from the rest of the institution, and to establish a high-class school of practical science in all its branches. Dr. Edward B. Aveling has been appointed to the charge of this laboratory, and intends forthwith to establish classes for practical instruction in all the science subjects required for the university, government, and other examinations.

THE first series of 500 select public teachers in France arrived in Paris on August 15 to visit the Exhibition, at the expense of the government. They are accompanied by 1,000 teachers of the same districts travelling at their own expense, but conveyed at half price by the various railway companies, and boarded in several Paris colleges. They were received at the Sorbonne, in the large hall, by M. Casimir-Périer, the Sub-Minister of Public Instruction, and lectured by M. Levasseur on the teaching of geography. They will be lectured on the teaching of French, of history, and on the organisation of lectures and public libraries. They will leave on Friday, and be succeeded by another set of teachers.

M. BARDOUX has issued a circular intimating that a special financial department has been created for facilitating the building of school-houses in the several French communes. A credit of 60,000,000 francs has been voted by the Chambers, and will be divided amongst the several municipalities that desire to improve or rebuild their public schools, on the condition that each should expend a sum of at least double that taken from the public exchequer.

PROF. A. WOLTMANN, of Prague, has accepted a call to the directorship of the Archæological Institute at Strasburg.

THE first experiment of an educational turn for children, about which we spoke some months ago, has given such good results that a new society is in process of formation at St. Petersburg for a similar purpose. Several eminent teachers of the Russian capital have offered their services to the society, which will yearly send out companies of children on educational travel, as well as parties of young ladies and young men who have finished their studies in secondary schools, or are following the courses of high schools.

THE ECLIPSE

THE telegram sent from Denver, signed by Professors Young and Watson, Dr. Draper, and myself, will have given an idea of the results which we think have been secured on the eclipse of this year. Since the telegram was despatched I have been engaged in making as many notes on the various points of detail as incessant travel and a temperature of 91° in the shade would permit. A long time must elapse before anything like a general view of the total work done is possible, but I think that the readers of NATURE may rely upon the correctness of what I have collected, though it is quite possible, as I have not succeeded in finding all the observers, that some errors may have crept in. And again, it is quite possible that the many dry plates taken and even yet not developed, may contain information of which at present we have no idea. To take an instance: we do not yet know whether Prof. Harkness's attempt to photograph the polariscopic phenomena presented by the corona was successful or not, for I learn at the Naval Observatory here that he is still at Fort Steele, handing over his camp equipment to the military, who all along the line have been placed in the most unreserved way at the disposal of the different parties by the express orders of Gen. Sherman himself, who takes the greatest interest in such inquiries, and is anxious to foster scientific inquiries as far as in him lies. Strange as it may seem, this is the expressed feeling of all the authorities here, from the Chief of the State downwards. In interviews with which I have been honoured, the President of the United States himself, the Secretary for War, Gen. Sherman, and other members of the Cabinet, have one and all insisted upon the importance of securing records of all possible natural phenomena, and expressed their gratification that such records have been secured in the present instance by Government aid.

I will begin the extracts from my notes by referring to the appearance of the Corona itself.

I give a rough sketch of what *I* saw of the corona with the naked eye (Fig. 1), slightly exaggerating the dimensions of the streamers to show the wind-vane appearance, which, to me, was almost perfect, being pointed at one end and bounded by parallel edges at the other; others, I may say, however, saw a resemblance to a fish's tail. These streamers vanished absolutely in the telescope (Fig. 2), as did the radiating lines in 1871; not a shred of them was left. Prof. Cleveland Abbe (lying on his back at a height of eleven feet on Pike's Peak; he had been sent down the day before from the summit, as the rarefaction of the air was too much for him) saw them, with the naked eye, extending to a distance of six degrees on either side, and their appearance suggested to him meteoric streams for their origin. Prof. Newcomb also saw them with the naked eye when he had hidden the corona behind a screen. To him they suggested the zodiacal light, or rather its nucleus near the sun, even if it extend beyond the orbit of the earth.

These streamers seem to have been seen by everybody, and were doubtless cosmical; a system at right angles to them (they lay along the ecliptic), and quite as bright, was recorded by many, though many of the best observers saw not a trace of them.

Here is a lesson, and one which affords an explanation of a great deal of eclipse work, connected with these outliers of the corona.

I had a magnificent view of the corona with a power of 50 on my 3¾-inch Cooke, and saw exquisite structure at the north and south points. Curves of contrary flexure started thence, and turned over, and blended with the rest of the corona, which was entirely structureless and cloud-like; the filamentous tracery which in India I observed till three minutes after totality had ended had all gone. Prof. Bass, however, tells me that by confining his attention to the same point for nearly the whole of totality, the structure came out, and seemed to pulsate like an aurora.

Prof. Hall is almost the only one who is under the impression that the corona of 1869 was less brilliant than this.

Mr. Burnham, who is an observer of the highest order, thus gives his opinion, which agrees with that of Prof. Young, who remarked its unusual faintness and lack of polar extension, and all the other American astronomers:—

"The coronal display was far less than in the eclipse of 1869, as seen at Des Moines, Iowa, by members of the *Times* party, and it bore a more striking resemblance, probably, to the eclipse of 1870, as seen at Gibraltar and in the Island of Sicily. The corona was, in fact, a mild affair, according to the observations of this party, as compared with that seen in other eclipses. A few protuberances were seen, and several bright streamers. On one side there was observed a bright pink ribbon or crescent. The traditional bright lines (the rays) and dark patches (the rifts) were not nearly as conspicuous as usual."

Mr. Burnham made another interesting observation which may prove one of considerable value in determining the nature of the corona. Anticipating that the star ζ Cancri would be very near to the sun, he made special efforts to see it, and was altogether successful, for it was distinctly seen through the corona.

General Myer, the distinguished head of the Army Signal Service, who had given orders to utilise his station on Pike's Peak for eclipse observations, observed the corona himself from the summit, and therefore, under conditions which have never been utilised before. He describes the corona as built up of five radial lines of a golden colour; beyond this in the direction of the ecliptic were prolonged bright silver rays. This was seen with the naked eye. In the telescope the appearance was quite different; a layer close to the sun, only of a light pink colour, was seen, and the long bright silver rays had disappeared. The greater elevation, thus, was more suited to a study of the structure than the lower levels, and at the same time the colour observed seems to have been slightly changed. In the pure air of the Peak, also, he saw the corona steadily for about five minutes after totality, and watched the moon cover the outer striated edge of the corona, which appeared, then, to be more golden than ever.

We next come to the Photographs.

Photographs of the corona and of its spectrum were

obtained at nearly all the stations. In order to give an idea of the extensive preparations which have been made, I may state what were Dr. Draper's photographic appliances as an instance of the equipment at one station.

In the first place there was a telescope of 5 inches aperture, and 78 inches focal length, especially corrected for photography, to get as complete a photograph of the corona as could be obtained by an exposure lasting

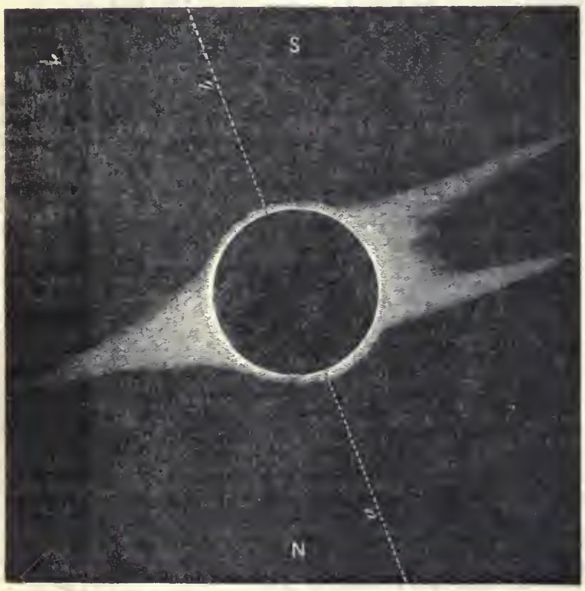

FIG. 1.—Naked eye.

during the whole of totality. This was during 165 seconds.

Next there was a large instrument which may be called a slitless "phototelespectroscope." This instrument consisted of an object-glass, composed of four lenses 6 inches in diameter and 21 inches focal length. The image of the sun at the focus was less than $\frac{1}{4}$ of an inch in diameter, and of extreme brilliancy. Before the rays of this lens reached the focus, however, they were intercepted by a Rutherfurd grating, about 2 inches square,

FIG. 2.—Telescope.

set at an angle of 60 degrees. This threw the rays to one side, and produced three images—a central one of the sun, and on either side of it a spectrum. One of these spectra was dispersed twice as much as the other, that is, would give a photograph of twice the length. This last photograph was actually about 2 inches long. With this instrument, mounted equatorially and driven by clockwork, if the light of the corona was due to gas, giving lines which lay in the actinic region of the spectrum, ring-formed images, one ring for each bright line, would be introduced. On the other hand, if the light of the corona arose from solid or liquid bodies, or was reflected light from the sun, a long band answering to the actinic region of the spectrum alone would be produced. If the light was partly from gas and partly reflected sunlight, a result partly of rings and partly a band would have been obtained.

As there was an impression that it was impossible to obtain a photograph of the spectrum of the corona, Dr. Draper, in order to give the best possible chance of

FIG. 3.—1, image of sun; 2, first order spectrum; 3, second order.

getting such a photograph, resorted to exceedingly sensitive materials, known as the lightning collodion process, furnished by the Messrs. Anthony, of New York. This involved a necessity of distilling a large part of the water used, because at Rawlins the water contains either alkali or sulphur, both of which are deleterious.

Since so many attempts were made, I had better confine my attention to the photographs. I have seen those of Prof. Hall and Dr. Draper. I will first deal with those of the corona itself. The former, taken by a dry-plate process, and, I believe, by means of a large apertured camera of short focus, are very admirable, and

FIG. 4.

show the structure at the north and south points most exquisitely.

One of Dr. Draper's was exposed during the whole of totality, and represents a corona somewhat like those seen in the photographs of the 1871 eclipse taken with a medium exposure. In another, by a fortunate shake of the instrument, a trace of the outline of the chromosphere was received.

Next I come to the Spectra; but first I may be permitted to refer to the only photographic contrivance which was possible for my light marching order. This was a small portrait camera with a lens of one inch aperture,

FIG. 5.

and a Rutherfurd grating of about 6,000 lines to the inch in front of it to act as a reflector and disperser.

I placed the camera and the attached grating on the ground in such a position that on the focusing screen I got the direct image of the sun at one edge of the plate, and running across the plate the spectra of the first and second orders on one side. A rough notion of what is seen on the plate when the sun is photographed thus will be gathered from Fig. 3.

Now if the corona had been built up of gases competent to give us lines with a spectroscope of ordinary construction, what I ought to get during an eclipse from

this instrument would have been something like Fig. 4, *provided I had a clockwork arrangement to drive it.* Without this contrivance the image and spectra will travel along the plate in the direction of the sun's motion—Let us suppose as here in Fig. 5.

It will be thus clear that, with this simple contrivance, the result obtained, if clock-work be employed, will be very similar in kind to that arrived at in Dr. Draper's more elaborate arrangement, to which attention has been drawn.

In the spectra, then, thus obtained, we had only one question to solve, as we all thought: we had to determine the position of the rings photographed in the first and second order spectra, or, at all events, in the first. Long before I developed my plate I knew what had happened. Dr. Draper, Prof. Thorpe, and myself, had photographed the spectrum—this I never doubted—but we had photographed as continuous a one as if a platinum wire, or ball, in a state of incandescence, had been in front of our instrument, instead of a shell of hydrogen gas 6′ high, as in 1869, and 10′ high, as in 1871.

Dr. Draper's plate was exposed during the whole of totality, to make assurance doubly sure. The continuous spectrum has no trace of a ring, though the plate was considerably over-exposed. In my own little photograph the continuous spectrum only is shown, and very clearly. While my plate was being exposed I held a duplicate grating close to the eye, expecting to see the rings as I saw them through five prisms in 1871. In first, second, and third order it was all the same—

Continuous spectrum,
Continuous spectrum,
Continuous spectrum ;

and it was this which told me of the gigantic change which had taken place in the atmosphere of the great body we were studying.

The remarkable phenomenon thus photographed was of course as remarked by the eye observers ; still bright lines were seen in the corona spectrum by one observer, using the term corona to represent everything outside the photosphere, and I make this remark because, whether the spectrum observed was that of the phenomenon which was visible or not I cannot say.

Prof. Young himself and many other observers saw the reversal of many lines at the moment of totality, thereby endorsing Pye and Maclear's observations of 1870 and 1871. After this, to all but Prof. Young the lines vanished utterly, and this was so absolute that in three parties there was consternation and fear, when nothing but a continuous spectra was seen, that something had gone wrong with the instruments.

Prof. Young saw 1474 very faint, *F without C*, and strangest of all, the H and K lines without the long calcium line. This is one of the most remarkable results of the eclipse, and must set students of solar physics to work on a new line. Young thinks the H and K lines were brilliant enough to suggest that the ring in this part of the spectrum photographed in the eclipse of 1875 was really due to them, and I am inclined to agree with him, though why the H and K lines should appear minus the longest line of calcium, passes comprehension, unless calcium is dissociated there from some cause of which at present we have no idea.

The discovery of a line in the ultra red by means of a thermopile, is another victory gained, and I sincerely hope that at the next eclipse Capt. Abney may use some "red molecules" to photograph it. Mr. Edison, with his wonderful tasimeter, also found indications of heat in the corona, but as he did not use a spectrum, he did not imitate Prof. Young in determining the exact position of the radiation.

We next come to the Dark Lines observed in the corona spectrum.

Janssen was the first to announce the fact that in the corona spectrum the chief Fraunhofer lines were to be seen. This observation was made on the Indian eclipse of 1871. The natural interpretation of this observation is that in the coronal atmosphere there are molecules sufficiently complex to reflect rays of every refrangibility, and that they do in reality reflect the solar light to us as it reaches them.

The observations on this point are a little doubtful, though it is held generally that the balance of evidence is in favour of their appearance. Prof. Barker, who observed with Dr. Draper at Rawlins, saw these lines at the moment that he was dumbfounded, as were most of the observers, at the absence of the bright ones. On the other hand at Prof. Newcomb's camp at Separation they were not traced, Commander Sampson seeing nothing but a perfectly continuous spectrum ; 1474, F, and even C being utterly invisible. If the corona gives us light containing the Fraunhofer lines, it can only do so because it reflects solar light. Let us next see, then, what the evidence as to Polarisation is.

When all the observations on this subject are collected we may hope for much new knowledge, but the matter was not finally settled this time, for here again was a surprise.

Professors Morton and Hastings had arranged to determine the quality of the polarisation observed, Prof. Harkness was to attempt to photograph the phenomena, while Prof. Wright set himself the difficult task of quantifying it. One observer was specially told off to settle the questions raised by Prof. Pickering's observations of 1870. I may commence by saying that these last observations suggest that in 1870 the instrument used by Prof. Pickering was out of order, so that now everybody agrees that there is polarisation.

I have not yet been able to learn anything of the results obtained by Professors Wright and Harkness as the latter used dry plates which were to be developed here, and the Las Animas party took a long mountain trip to shake off the bad effects of a long camping on an alcali plain, and so did not put in an appearance at Denver.

Prof. Morton got radial polarisation most distinctly as I did in India in 1871. The *amari aliquid* is to be found in Prof. Hastings' results, which will be best seen from the following account obligingly placed at my disposal by Prof. Bass, one of his party :—

"The most important and unexpected result of the expedition was reached by Dr. Hastings in his polariscopic observations. It will be remembered that in previous expeditions, and by many observers in the present eclipse, only a few seconds were devoted to the examina-

tion of the corona for polarisation, and this by a bi-quartz or a Savart polariscope, held in the hand so as to take in the whole corona in one view. In the organisation of the expedition, Dr. Hastings was requested to prepare a plan by which the question as to whether the polarisation of the corona was radial or tangential, or absent, could be definitively settled. This was accomplished by an arrangement of apparatus essentially novel.

"The four-inch telescope had a Savart polariscope at its eye end. A diaphragm perforated with holes, 3′, 4′, 5′, 8′, 10′, 16′ was interposed between the polariscope and the objective, and the polarisation phenomena of a definite and limited portion of the corona were thus seen. Diaphragms of 3′ and 5′ were alone used. The telescope was pointed by Lieut. Very to six points, the first one above the sun and 50′ from the circumference; the second one 25′ from the circumference and 45° from the vertical; the third $1\frac{1}{2}'$ from the sun and to the right of it; the fourth 16′ from the sun and to the right of it; the fifth 16′ from the sun and 135° from the vertical; the sixth 8′ from the sun and 135° from the vertical. These points were selected before the eclipse, but it was not known to Dr. Hastings in what order they would be viewed, so that the readings were absolutely free from bias. The position of the pointer of the polariscope was carefully verified before and after the totality. The readings were reduced immediately, and each reading (which was, as is evident, independent of every other) agreed in showing that the plane of polarisation was perpendicular to the sun's radius through the point examined—that is, *tangential*—a most unexpected result, about which, however, there is no doubt whatever. Four of the readings were made with a dark band in the centre, and two with a bright band. This result does not agree with others from the same eclipse, for the reason that in the method adopted by Prof. Morton, Mr. Lockyer, and others, there was, first, no means adopted for isolating a definite portion of the corona and determining its special polarisation. Second, that in the use of the Savart form, the phenomena of radial or tangential polarisation alike present bands radial to the sun. Third, that, with the bi-quartz, the field is so small that it becomes extremely difficult to interpret the tints of colour seen, if indeed any are seen. The novel fact was shown, by the use of this method, that the polarisation of the corona was exceedingly strong near to the sun's limb (one and a half minutes), and was relatively weak far from it."

I believe that no one is more astonished than Prof. Hastings himself at the result of his work, which, it has been laughingly said, goes to demonstrate the existence *ice crystals* in the corona. With reference to the remarks made on my 1871 work in the foregoing, I may add that I used a bi-quartz and a large field, so that the objections raised to the method do not apply.

This brings me to the end of my notes for the present on the photographic, spectroscopic, and polariscopic results obtained. Of course there was a whole world of wonders outside these fields of inquiry.

The view of the shadow of the moon from the summit of Pike's Peak cleaving its way along the lower air has been described to me as one of the most striking phenomena which it is possible to witness or imagine. The shadow, the boundary of which was seen curved, was preceded and followed by a spectrum. Where I was, nearly 8,000 feet high, and therefore a little over mid-height, there was no effect on the air, but after the close of totality the shadow was observed passing over clouds near the horizon. I may add, however, that the phenomena at the beginning and end of totality hardly existed for me, for I had to uncover and cover my photographic plates at those times.

It was not to be expected that in this country, where the anxiety for news and views seems always to be at fever heat, the astronomers would be allowed to quit their stations without giving an idea of the tendency of their work, and even its connection with the torrid temperature through which we have had to make our dusty way, or in which we have had to exist when locomotion had become impossible.

The utter disappearance of the large bright red corona of former years in favour of a smaller and white one in this year of minimum, struck everybody. Indeed it is a remarkable thing that after all our past study of eclipses this last one should have exhibited phenomena the least anticipated. It isolates the matter that gives us the continuous spectrum from the other known gaseous constituents. The present eclipse has accomplished, if nothing else, the excellent result of intensifying our knowledge concerning the running down of the solar energy. With the reduction of the number of spots or prominences for the last four years the terrestrial magnetism has been less energetic than it has been for the preceding forty years, while at both ends of this period we have had famines in India and China.

As the sun is the great prime mover of earth, and as every cloud, every air current depends upon it, its present quiet condition is worthy of the most minute study. The absence of lines from the corona spectrum shows a great reduction in the temperature of the sun, and such a marked change in the sun should produce a corresponding change on the earth, so that the associated terrestrial phenomena should be carefully observed. Hence I regard this eclipse as the most important that has been observed for many years as it throws much needed light on many points hitherto obscured in doubt.

Prof. Morton, of the Stevens Institute of Technology, remarked that the thing which impressed him most was the very curious character of the result; while on former occasions there has been projected into the space surrounding the sun a quantity of self-luminous gaseous matter which has no fixed place there, we now see that this was merely a temporary occupant which has, either by diffusion into space or absorption into the body of the sun, been removed. He also holds that the marked changes in the sun's condition would seem to call for corresponding marked changes in the condition of the earth. The results, in fact, recall to his mind one of the early theories of the maintenance of the sun's heat, which was that it was maintained by the impact of meteoric matter constantly falling in upon the sun from surrounding space. The quantity of heat produced by such an infall may be realised from the fact that a body so falling would develop by impact as much heat as 5,000 times its weight of carbon burnt in oxygen. Portions of the meteoric matter in the shape of meteorites fall upon the earth, and we thus know that most of them consist largely of iron, containing considerable quantities of absorbed gases; others are of a metallic character and devoid of such gases. If, now, we suppose that for a considerable period the sun's fires were fed with hydrogen-charged faggots, and then again that the main supply was of mineral matter, we might have at first a far-reaching atmosphere

of gas, such as has appeared hitherto, and at another time this might be absent, which seems to be the case at present.

He further adds that if such changes go on indefinitely it may not be irrational to inquire whether they may not in future produce such extraordinary climatic conditions in the earth as geology teaches us have existed in the ages of the past.

Prof. Young was careful not to commit himself to any decided connection between solar and terrestrial climatic changes; he, however, certainly concurs with me that the corona is fainter and the gaseous elements far less conspicuous than that observed at previous eclipses, and acknowledges that the different condition of the corona proves a change in the condition of the sun, as the corona acts with it in a sort of sympathy. Dr. Draper is resolute on the other side. He is reported to have said:—

"It is rather singular while the sun has been in such a quiescent condition for more than two years, that we have not seen more changes in the climate of the earth. This would seem to show that the abnormal condition of the sun at the maximum period of sun-spots, which occurs every eleven years, counts for but little against the total amount of heat that is sent out from the sun at all times. The present observations go to show that the activity or quiescence of the sun makes no perceptible difference in the earth's condition. I do not regard this most marked change in the corona as portending any change in the condition of either climate or crops."

Finally, on this whole question, I may remark that I have been not a little astonished to find how slowly European work percolates among the men of science here. I have met with few who are familiar with Meldrum's admirable work, and the discussion to which it has given rise. Still it is a great thing that at all events the cycle of solar changes has forced itself so markedly upon public attention.

For myself, as I have ever regarded sun-spots as

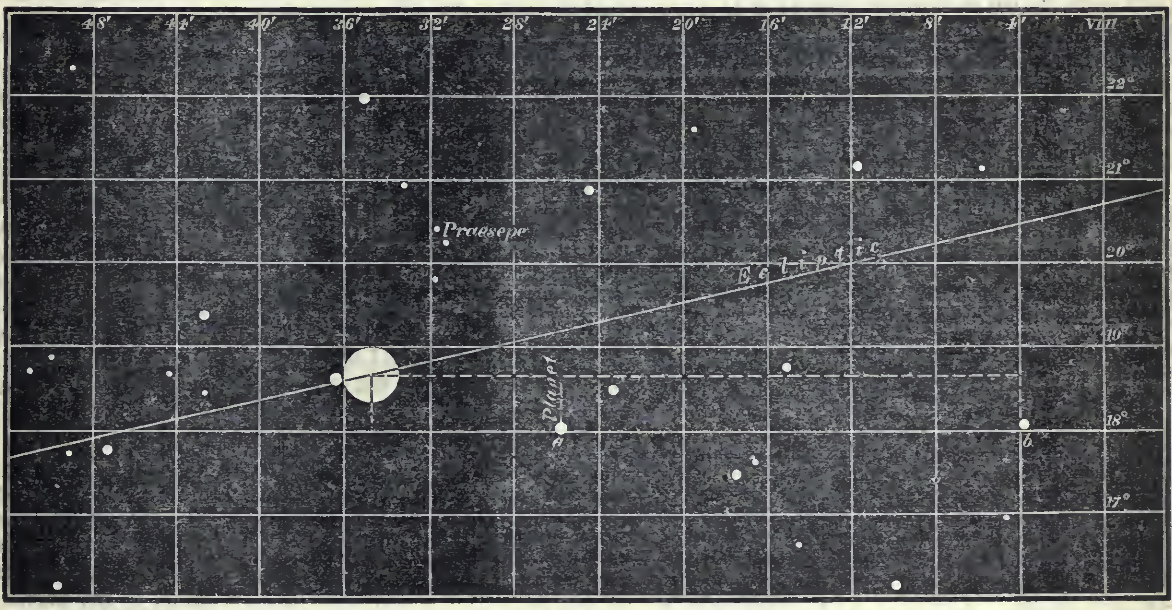

FIG. 9.

down-rushes—a term to which I still adhere—I am well content to see this view indorsed by such a chain of facts as the corona has now supplied. In spot-maximum years we have violent up-rushes of gas from the sun's interior, and the corona is mainly built up of such gas. Further, we have spots, and, if these are not evidences of the return convection currents, we have none other. In spot-minimum years, such as the present, we have no up-rushes, and the corona contains no gas, and there are no spots. Spots, then, are only observed when we have a right to look for the return of the upward current, about which there is no doubt, and the rate of which we have measured.

But if this puts beyond all question, as I hold it does, the nature of spots, on the other hand, the separation of the gaseous from the continuous spectrum of the corona indicates that we have yet much to learn of the temperature and nature of the corona when the spots are absent.

So much, then, touching the progress of solar matters during the eclipse of 1878. I have not yet, however, done with the observations.

There is little doubt, I think, that an intra-Mercuria planet has been found by Prof. Watson. If it will fit one of Leverrier's orbits, and should turn out to be Vulcan, no doubt astronomers will be able to keep a firm grasp upon it, and sooner or later its elements will be determined.

Prof. Watson, of Ann Arbor, whose belt, as the papers here put it, is graced with the scalps of I know not how many minor planets, broke off work on a planet beyond Neptune to come to discover one inside Mercury. He went with me in Mr. Silvis' railway photographic car from Rawlins to Separation on the morning of the eclipse, intending to observe with me at the station we were determined to occupy, with our light equipments, as the number of detached clouds visible at the time of totality on the pre-

vious days had strongly shown the advantage of separating the parties as much as possible. We chose a spot to leeward of one of the enormous water tanks of the Union Pacific Railway, which form the chief features in the interesting but desolate plains in that region, over which the wind sweeps at times with incredible violence.

On reaching our destination we found Prof. Newcomb, whose camp was about a mile away, and it was then agreed that as both he and Prof. Watson were to hunt for the planet they had better be together, so I lost his company during the eclipse.

Prof. Watson's plan of operation was to sweep south of the sun and observe all the stars in the map, a part of which is here reproduced (Fig. 6), and to refer the position of any new body to the stars, or, if possible, to the sun itself. For this purpose, with the assistance of the Rawlins carpenter, he armed his equatorial with paper circles and brass wire pointers. He commenced operations to the left of the sun and saw the stars marked, but none others. Then sweeping out to the star marked *b* he noticed on his return another not on the chart, marked *a*. He then made three marks on his right ascension paper circle, on the spots occupied by the pointer, when the sun, *a* and *b*, were successively brought into the centre of the field. He next determined the difference of declination in the same way between the sun and *a*, having the additional help that *a* was nearly in the same declination as *b*. He then repeated his R.A. measures, and called Prof. Newcomb, but the eclipse was over before anything more could be done. I give this statement from memory only (as I was too busy to make notes at the time), as I heard it soon after the eclipse at the camp, before the telescope was dismounted. It is probable that subsequent careful measures of the circles may alter the place—

R.A. 8h. 26m.
Dec. + 18° 00′

I telegraphed to you, somewhat, but the alteration will be small.[1]

Since arriving here I have learned that Mr. Swift, of Rochester, a well tried observer, also saw the planet. The first account I read of his work was as follows:—

"This gentleman made a very careful search for Vulcan, scanning the heavens very closely with his splendid comet eye-piece, made by the celebrated Gundlach, but he saw nothing of it. He did, however, see, about three degrees from the sun, two stars not down in the charts or star maps, and about as bright as the pole star—they were pointing directly towards the sun. On attempting to re-find them, he was prevented by a little cloud."

Since then, however, another fuller account of his work has appeared, from which I gather that about one minute after the commencement of totality two stars caught his (Mr. Swift's) eye about three degrees, by estimation, south-west of the sun. He saw them twice, and attempted a third observation, but a small cloud obscured the locality. The stars were both of the fifth magnitude, and but one is on the chart of the heavens. This star he recognised as Theta in Cancer. The two stars were about eight minutes apart. There is no such configuration of stars in the constellation of Cancer. In 1859 the French astronomer, Lescarbault, claimed that he had seen an intra-Mercurial planet crossing the sun's disc. He related his discovery to Leverrier, who became a firm believer in the existence of such a planet. The perturbations of Mercury's orbit demand such a planet as Leverrier named Vulcan. The star Mr. Swift saw may have been the same that was seen by Prof. Watson, who was located at Rawlins, Wy. T.

Mr. Swift possessed a comet eye-piece of very flat and large field, and distinct to the very edge. It was made in Rochester, and to it and his blunder in failing to untie his instrument, he believes he owes his success.

The instrument used in the search for Vulcan by Prof. Holden proved to be inadequate to show all the stars on the Washington star map, owing to the brightness of the corona. The space where the planet seen by Prof. Watson was, was four times swept over, but so near to the sun as this, a four and a-half magnitude star was not to be seen. A space of 10° in declination by 35° in right ascension was twice swept over.

Here, again, we get an idea of the thoroughness with which the work has been planned and executed.

It would be wrong to conclude these hurried notes without stating that, from the day in which I landed in New York to the present time, I have become everybody's debtor for acts of kindness, which have touched me greatly. This great country is a land of true courtesy, for which I here express my gratitude, not only to my scientific brethren, and chiefly to Dr. Draper, General Myer, and Prof. Newcomb, whose guest I have been, but to hundreds to whom I have been a stranger and unknown.

As significant of the keen interest taken in the eclipse by all classes here, I may mention, in conclusion, that on the Sunday before the event prayers for fine weather were offered in all the churches of Denver.

Washington, D.C., Aug. 8 J. NORMAN LOCKYER

[1] On going to press we receive a letter from Prof. Watson, dated Ann Arbor, August 14, stating that the result of more careful examination gives —Washington M.T., July 29, 5h. 16m., R.A, 8h. 26m. 54s., Dec. + 18° 16′.

AS I have been recently giving attention to the subject of solar spectroscopy in consequence of my discovery of oxygen in the sun, it seemed desirable to take advantage of the total eclipse of July 29, to gain as precise an idea as possible of the nature of the corona, because the study of that envelope has been regarded as impossible at other times. The main point to ascertain was whether the corona was an incandescent gas shining by its own light, or whether it shone by reflected sunlight.

For this purpose I organised an expedition, and was fortunate enough to secure the co-operation of my friends Professors Barker and Morton, and Mr. Edison. The scheme of operation was as follows: (1) the photographic and photo-spectroscopic work, as well as the eye slitless spectroscope were to be in charge of my wife and myself; (2) the analysing slit spectroscope was in charge of Prof. Barker, with the especial object of ascertaining the presence of bright lines or else of dark Frauenhofer lines in the corona; (3) the polariscopic examinations were confided to Prof. Morton, who was also to spend a few moments in looking for bright or dark lines with a hand spectroscope; (4) Mr. Edison carried with him one of his newly-invented tasimeters with the batteries, resistance-coils, Thomson's galvanometer, &c., required to determine whether the heat of the corona could be measured.

This entire programme was successfully carried out,

and good fortune attended us in every particular. The results obtained were: (1) the spectrum of the corona was photographed and shown to be of the same character as that of the sun, and not due to a special incandescent gas; (2) a fine photograph of the corona was obtained, extending in some parts to a height of more than twenty minutes of arc, that is, more than 500,000 miles; (3) the Frauenhofer dark lines were observed by both Professors Barker and Morton in the corona; (4) the polarisation was shown by Prof. Morton to be such as would answer to reflected solar light; (5) Mr. Edison found that the heat of the corona was sufficient to send the index beam of light entirely off the scale of the galvanometer. Some negative results were also reached, the principal one being that the 1474 K, or so-called corona, line was either very faint or else not present at all in the upper part of the corona, because it could not be observed with a slitless spectroscope, and the slit spectroscope only showed it close to the sun.

The general conclusion that follows from these results is that on this occasion we have ascertained the true nature of the corona, viz., it shines by light reflected from the sun by a cloud of meteors surrounding that luminary, and that on former occasions it has been infiltrated with materials thrown up from the chromosphere, notably with the 1474 matter and hydrogen. As the chromosphere is now quiescent this infiltration has taken place to a scarcely perceptible degree recently. This explanation of the nature of the corona reconciles itself so well with many facts that have been difficult to explain, such as the low pressure at the surface of the sun, that it gains thereby additional strength.

The station occupied by my temporary observatory was Rawlins (lat. 41° 48′ 50″, long. 2h. 0m. 44s. W. of Washington, height 6,732 feet above the sea), on the line of the Union Pacific Railroad; because, while it was near the central line of totality, it had also the advantages of being supplied with water from the granite of Cherokee mountain, and of having a repair shop, where mechanical work could be done. I knew by former experience that the air there was dry and apt to be cloudless; in this particular our anticipations were more than fulfilled by the event, for the day of totality was almost without a cloud and the dew-point was more than 34° F. below the temperature.

The instruments we took with us were as follows, and weighed altogether almost a ton:—1st. An equatorial mounting, with spring governor driving clock, lent by Prof. Pickering, Director of Harvard Observatory. 2nd. A telescope of 5¼ inches aperture and 78 inches focal length, furnished with a lens specially corrected for photography, by Alvan Clark and Sons. 3rd. A quadruple achromatic objective of 6 inches aperture and 21 inches focal length, lent by Messrs. E. and H. T. Anthony, of New York. To this lens was attached a Rutherfurd diffraction grating nearly 2 inches square, ruled on speculum metal. The arrangement with its plate-holders, &c., will be designated as a phototelespectroscope. 4th. A 4-inch achromatic telescope with Merz direct vision spectroscope, brought by Prof. Barker from the collection of the University of Pennsylvania. 5th. A 4-inch achromatic telescope, also brought by Prof. Barker; to it was attached Edison's tasimeter. Besides these there were polariscopes, a grating spectroscope, an eye slitless spectroscope with 2-inch telescope, and finally, a full set of chemicals for Anthony's lightning collodion process, which, in my experience, is fully three times quicker than any other process.

The arrangement of the phototelespectroscope requires further description, for success in the work it was intended to do, viz., photographing the diffraction spectrum of the corona, was difficult, and, in the opinion of many of my friends, impossible. In order to have every chance of success it is necessary to procure a lens of large aperture and the shortest attainable focal length, and to have a grating of the largest size adjusted in such a way as to utilise the beam of light to the best advantage. Moreover, the apparatus must be mounted equatorially and driven by clockwork, so that the exposure may last for the whole time of totality, and the photographic work must be done by the most sensitive wet process. After some experiments during the summer of 1877 and the spring of 1878 the following form was adopted:—

The lens being of 6 inches aperture and 21 inches focal length, gave an image of the sun less than ¼ of an inch in diameter and of extreme brilliancy. Before the beam of light from the lens reached a focus it was intercepted by the Rutherfurd grating set at an angle of 60 degrees. This threw the beam on one side and produced there three images—a central one of the sun, and on either side of it a spectrum; these were received on three separate sensitive plates. One of these spectra was dispersed twice as much as the other, that is, gave a photograph twice as long. This last photograph was actually about two inches long in the actinic region. If now the light of the corona was from incandescent gas giving bright lines which lay in the actinic region of the spectrum, I should have procured ring-formed images, one ring for each bright line. On the other hand if the light of the corona arose from incandescent solid or liquid bodies, or was reflected light from the sun, I was certain to obtain a long band in my photograph answering to the actinic region of the spectrum. If the light was partly from gas and partly from reflected sunlight, a result partly of rings and partly a band would have appeared.

Immediately after the totality was over and on developing the photographs, I found that the spectrum photographs were continuous bands without the least trace of a ring. I was not surprised at this result because during the totality I had the opportunity of studying the corona through a telescope arranged in substantially the same way as the phototelespectroscope, and saw no sign of a ring.

The plain photograph of the corona taken with my large equatorial (exposure 150 seconds) on this occasion shows that the corona is not arranged centrally with regard to the sun. The great mass of the matter lies in the plane of the ecliptic but not equally distributed. To the eye it extended about a degree and-a-half from the sun toward the west, while it was scarcely a degree in length toward the east. The mass of meteors, if such be the construction of the corona, is therefore probably arranged in an elliptical form round the sun.

For the fortunate results of this expedition we are not a little indebted to the railroad and express companies. The Pennsylvania, the Chicago and North-western, and the

Union Pacific railroads, the Pullman Palace-Car Company, and the American and Union Pacific Express companies made the most liberal arrangements, and Mr. Galbraith, the superintendent of the Repair Works at Rawlins, gave us the free use of his private house and grounds. Of the citizens of Rawlins it is only necessary to say that we never even put the lock on the door of the observatory, and not a thing was disturbed or misplaced during our ten days' residence, though we had many visitors. They sent us away with a serenade. HENRY DRAPER

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Floating of Solid on Molten Metal

I OBSERVE in NATURE (vol. xviii. p. 397) a note of some experiments on this subject. The results of these experiments (unless with lead) are, I think, very similar to some which I have made, and described in your pages (see NATURE, vol. xvi. p. 23), viz., that with *heavy pieces* the metal first *sank* and then *rose to surface*; with light pieces, the "skin" formed on the surface of the ladle was sufficient to keep them afloat. From these experiments I drew the conclusion that the cold solid metal was specifically *heavier* than the molten metal, but after a short immersion, depending on size of pieces, these pieces had *expanded* by the great heat around them so as to have *their bulk increased sufficiently* to enable them to float. My experiments with solid pieces of lead showed that they *sank* and did not come to the surface, and could be felt lying at bottom. Pieces of sheet lead rolled up floated.

In some recent experiments which I made, I found that *cold* pieces of steel rails placed in a furnace of molten steel sunk at first and floated afterwards, but that *hot pieces floated*, and did not sink. W. J. MILLAR

100, Wellington Street, Glasgow, August 10

A Meteorite ?

THIS day, at 12.15 P.M., I was considerably startled by what was to me a remarkable phenomenon. The weather had been very "thundery" all the morning, and heavy rain was falling in torrents. I sat at my desk by a window looking out upon a court inclosed by high walls. Chancing to look out of the window I heard a sharp report, just like the crack of a Snider rifle sounding immediately outside, followed instantaneously by the descent of a ball of fire about the size of an ordinary gas-lamp globe. This fell vertically and with lightning speed, but when just on a line with the centre of my window burst into a splendid mass of rays, whitish-blue in colour, and of dazzling brilliancy. That is all I can tell you about it. Every one in the house heard the report, and quite a temporary panic ensued. No material effect of the meteorite's presence can be found.

Perhaps some of your readers may be able to explain the phenomenon. J. HARRIS STONE

67, Chandos Street, Strand, August 23

The Australian Monotremes

THE *Tachyglossus* was shot by me near Georgetown, in lat. 18° S. I have found it inhabiting the porphyritic ranges (Newcastle and Mount Turner) in this locality, where they are rather numerous. In my letter (NATURE, vol. xvi. p. 420) I should have written "integumentary" pouch. The *Orinthorhynchus paradoxus* I saw floating with its bill above water in a lagoon between Georgetown and Normanton, 150 miles west of the former town.

Owing to the noise made by my detachment in riding up, I was unable to capture this specimen, but I do not despair of securing one on my next trip westward. I certainly believe the *Tachyglossus* extends throughout the length of the Cape York peninsula on the east, and through the Gregory, Leichhardt, and Cloncurry ranges to the southward and south-westward of Georgetown. Its habit of burrowing beneath rocks precludes the possibility of its occurrence on the Lower Gilbert and Flinders River plains.

"P. L. S." will find my "notes" on this subject in the Linnæan Society's *Journal*, as I sent them, accompanied by the skull of an adult female, to the Society in March last.

Georgetown, June 1 W. E. A.

Microphone in Indirect Circuit

IT is not absolutely necessary that the microphone should form part of the direct circuit. It works just as well if connected so that, when the carbons are not touching, the whole of the current goes through the telephone. When the carbons are together a small portion will of course leak through them; upon this leakage depends the rise and fall of tension in the receiver. For some experiments it is even better to work the microphone in this indirect manner, as the circuit always remains closed, and prevents, in a great measure, the *jarring* noise resulting from a break. ALFRED CHIDDEY

Bristol Mining School, August 19

OUR ASTRONOMICAL COLUMN

THE SATELLITE OF NEPTUNE.—We here present in a tabular form the means of determining the approximate position and distance of the satellite of Neptune, with respect to the primary for any time during the months of September and October, or indeed by extending the epochs subjoined, for any time during the present opposition. The argument u is the distance of the satellite from the ascending node of the orbit upon the earth's equator, and $u = 0°$, at these Greenwich mean times :—

		h. m.			h. m.
Sept. 4	...	18 38·3	Oct. 4	...	3 52·0
,, 10	...	15 41·0	,, 10	...	0 54·7
,, 16	...	12 43·8	,, 15	...	21 57·5
,, 22	...	9 46·5	,, 21	...	19 0·2
,, 28	...	6 49·3	,, 27	...	16 3·0

The motion of u in one day is 61°·257, in one hour 2°·552, and in one minute 0°·0425. Having determined the value of u from these epochs and motions for the proposed time of observation, the angle of position and distance of the satellite from the centre of the planet may be taken from the following table, in which the first and second columns of angles apply to the respective columns of the argument u :—

Arg. u.		Angle of position.		Distance.	Arg. u.		Angle of position.		Distance.
°	°	°	°	"	°	°	°	°	"
0	180	71·6	251·6	9·8	90	270	29·8	209·8	15·0
10	190	63·1	243·1	11·7	100	280	25·0	205·0	13·6
20	200	56·9	236·9	13·5	110	290	18·9	198·9	11·8
30	210	52·0	232·0	14·9	120	300	10·6	190·6	9·9
40	220	48·0	228·0	16·0	130	310	358·2	178·2	8·0
50	230	44·3	224·3	16·7	140	320	338·9	158·9	6·4
60	240	40·9	220·9	17·0	150	330	311·7	131·7	5·8
70	250	37·5	217·5	16·8	160	340	284·2	104·2	6·4
80	260	33·8	213·8	16·1	170	350	264·4	84·4	7·9
90	270	29·8	209·8	15·0	180	360	251·6	71·6	9·8

The period of revolution of the satellite is 5d. 21h. 2·74m., and by successive additions of this period the epochs may be continued for November or later.

As an example of the application of the table, suppose it is desired to know the approximate position of the satellite on September 14 at Greenwich midnight. Strictly the time for aberration should be deducted, which, in minutes, is given by [0·9189] × log. distance of Neptune from the earth—this log. distance being taken from p. 269 of the *Nautical Almanac*. In the present case we find 4h. 1·9m. to be deducted from 12h., so that

the time to be used in the calculation is September 14, 7h. 58·1m. This time follows the epoch in the above table by 2d. 13h. 36·4m., and with the motions already given, the value of u corresponding to this interval is found to be 225°·34, with which we enter the table and find the angle of position 226°, and the distance 16″·4. A direct calculation from Prof. Newcomb's tables of the satellite for the reduced Greenwich time gives 226°·4 and 16″·4.

NOTES

THE Chemical Society have lately made the following grants from their Research Fund:—50*l.* to Dr. Tilden, for an investigation into the chemical nature of the terpenes; 50*l.* to Mr. W. N. Hartley, for apparatus and materials required in carrying on a research on the action of organic substances on the ultraviolet rays; 30*l.* to Dr. W. Ramsay, for determining the electric conductivity and resistance of solutions of salts at different temperatures; 20*l.* to Mr. W. Jago, for the purchase of apparatus required for carrying on a research on the organic matter in sea-water; 10*l.* to Mr. W. A. Shenstone, for an examination of certain reactions of brucine and strychnine.

IT is understood that Signor d'Albertis has parted with the whole of the extensive zoological collections made during his two last expeditions up the Fly River, New Guinea, to the Marquis G. Doria, of Genoa, who will, no doubt, deposit them in the Museo Civico of that city, of which he is the founder and principal benefactor. These collections were first offered to the British Museum. Signor d'Albertis is now making arrangements for the publication in London of a narrative of his adventures in New Guinea.

WE regret to hear that the valuable collection of Chinese birds made by the late Mr. Robert Swinhoe, F.R.S., is still undisposed of. It was offered, we are told, to the British Museum, but, as too often happens in such cases, declined. It would be greatly to be lamented if this collection, which contains many types of species first described by Mr. Swinhoe, and the originals of his numerous papers on Chinese ornithology, should pass out of the country. It certainly ought to have been acquired for the national collection, even if a little more than what was considered its full value had had to be paid for it.

WE understand that the authors of the "Unseen Universe" are at present engaged on a work intended to serve as a sequel to that well-known volume.

WE are requested to state that Sir Joseph Whitworth having expressed a desire that some important alterations should be made in the conditions of his scholarships, the detailed rules for carrying out his wishes are now under consideration. They will be published as soon as possible; but in order to prevent disappointment this notice is given. No important changes will be made in the conditions of the competitive examination in May, 1879. But the conditions of the tenure and of the amount of the scholarships may be somewhat modified.

THE meeting of the French Association for the Advancement of Science was inaugurated in the large hall of the Sorbonne by an address by M. Fremy on Soda and Steel in 1878. The address was well received by a large audience, but it is generally regretted that the president did not take a subject of wider bearing for his address. MM. Virchow and Haeckel were present during the address. It is the first time that German men of science have taken part in French public assemblies in their private capacity. M. Gambetta was also present. Commandant Perrier gave a sketch of the work done at the last year's meeting of the Association. The number of members is now 2,384, the income for 1877 was 58,000 francs, and its capital 224,897 francs. The grants for 1877 amounted to 13,850 francs. A part of the effect of this scientific assembly is lost this year on account of the number at the Trocadéro, and the multitude of objects demanding the attention of Paris visitors. The morning sittings of the Meteorological Section are held at the Lycée St. Louis, and the evening meeting at the Trocadéro as a Congress of the Exhibition. One of the most interesting addresses will no doubt be that delivered by Dr. Janssen on celestial physics; and he will also give the substance of the papers read by him before the British Association. There are two candidates for the presidentship of the meeting of 1880, M. Krantz, Director of the Exhibition, and Col. Laussedat, of the Engineer service. Very probably the former will be successsful. Several cities are competing for the honour of receiving the Association in 1880. It seems probable that it will cross the Mediterranean to Algiers; M. Krantz is spoken of as the intended Governor-general of Algiers after the close of the Exhibition. Next year's meeting will take place at Montpellier under the presidency of M. Bardoux, the Minister of Public Instruction. On Sunday the Congress visited the Paris Observatory and the Meteorological Observatory at Montsouris.

AT the general meeting of the International Botanical and Horticultural Congress held at the Trocadéro, Paris, on the 16th inst., M. A. de Candolle was elected president. A *soirée* or reception was held on the evening of the 16th, and the members of the Congress went on the 18th to Sagrez, the residence of M. A. de Lavallée, president of the organising committee, by whom they were most hospitably entertained. The collection of hardy woody plants at Sagrez is unique in completeness in every sense.

ON Thursday last Mr. Cunliffe Owen was entertained at luncheon by some of the leading U.S. exhibitors at the Paris Exhibition, on board Capt. Boyton's yacht. Governor M'Cormack, in proposing Mr. Owen's health, spoke very highly of his executive abilities, and his courtesy towards the Americans, and attributes much of the success of the exhibits of English-speaking people to his energy, skill, tact, and good management.

IN the *Times* of August 13 an account is given of the working of the Mallory propeller, a very ingenious mechanical device for propelling and steering a ship in any direction by means of one and the same apparatus, recently brought over to England from America by its inventor, Col. William H. Mallory, of the United States army. It consists of a vertically swivelled screw propeller of peculiar construction, by the aid of which a vessel can be moved sideways, turned rapidly on a circle whose diameter is the ship's length, and can be made to advance or retire with equal rapidity. We cannot see any reason why this propeller may not be very useful for small vessels and others whose turning is more important than speed and sea-going qualities. That it will ever replace the direct propeller seems improbable, as there are three distinctly bad points about it:—1, the gear, which entails a loss of at least ten per cent. of the power; 2, the engines working on to a vertical shaft; 3, the engines being over the counters, which would render the ship very uneasy in a rough sea. Besides this, no vessel would go to sea without a rudder to use in case her engines broke down. On the other hand, the propeller presents many advantages for harbour work, and for such things as rams and torpedo boats.

WE learn from *Harper's Weekly* that, for the purpose of prosecuting biological researches, Prof. A. Agassiz has lately completed a superb establishment near his residence at Newport, wherein every device that experience could suggest has been brought to bear for the convenience of investigators. A building 45 by 25 feet has been erected on the side of a bay making up from the entrance to Newport Harbour, and provided with the purest of sea-water by means of a steam-pump, which keeps a tank constantly filled. The tables are covered with a series of

tiles of different colours, so that the minute animals of different shades can be the more readily overhauled when emptied upon them. The shelves in the laboratory are all of glass, the tanks are of slate, the conducting pipes are of iron, lined with a composition of rubber, which it is believed will protect them against corrosion. These tables are all well lighted, and are available for students, whom Mr. Agassiz invites to share his facilities. Four persons, in addition to himself, at present occupy the laboratory in prosecuting their special researches. There is, probably, no one of the many buildings erected here and in Europe for the prosecution of biological research so elegantly and thoroughly equipped as that to which we refer.

PROF. F. E. NIPHER, of Washington (U.S.) University, has undertaken a magnetic survey of the state in connection with the weather service. The work will require about three years to complete, and he contemplates getting over one-third of the state this summer. He will establish about twenty or twenty-five magnetic stations, to determine the dip of the magnetic needle and the deflection from the magnetic meridian. The professor started out on the survey early in July, accompanied by five or six students from Washington University, who will act as the assistants. He has received a complete set of instruments from the United States Coast Survey, consisting of a dip-needle and declination needle, with theodolite. The party will first go to St. Charles, and up the North Missouri railroad, taking in a territory as far west as Chillicothe, and embracing among the points of observation Hannibal, Macon City, Mexico, Columbia, Fulton, Kirksville, Moberley, and other eligible points.

MR. AUGUSTUS FENDLER, whose collections of plants, made thirty years ago in the vicinity of Santa Fé, were made known by Prof. Gray, and who for many years resided in Venezuela as a botanical collector, is now prosecuting similar work in the Island of Trinidad, devoting himself to the gathering of ferns and fern-like plants. Sets of the first series of these, embracing the first thirty-eight species, are procurable at a moderate price from the curator of Harvard University Herbarium, Cambridge, Massachusetts. They have all been named by Prof. Eaton, of Yale College.

SOME months ago we gave an account of the explorations of a young American, Mr. Herbert H. Smith, on the Amazon, referring to some geographical discoveries made by him, as also to his success in securing a large series of insects. Mr. Smith left New York on July 6 for Brazil, first to complete his work on the Amazon, and then to proceed to the southern provinces of Brazil.

A VIOLENT earthquake is reported from Innspruck. It occurred on the 9th inst. at 12.40 P.M., and was accompanied by loud subterranean noise. At 9 A.M. on the 26th, earthquake shocks were felt over a great part of Belgium and Holland, and in Rhenish Prussia at about 11 A.M. A shock of earthquake was felt at nine on the morning of the 26th inst. at Liége, doors and windows being much shaken and chairs disturbed. It was also felt at Elberfeld, Cologne, Osnabrück, and Barmen. At Barmen houses were upreared, roofs displaced, furniture shaken, and goods in the shop windows overturned. The shocks were repeated about eleven at Elberfeld, Düsseldorf, Cologne, and Bonn.

AT Halberstadt a remarkable Fata Morgana was observed on the 5th inst. at 7.10 P.M. The phenomenon is described by an eye-witness, who states that in a stratum of cloud in the direction of the Brocken both house and tower standing on the summit of that mountain were reproduced in distinct outlines and on a gigantic scale; even the windows could be recognised. The duration of the phenomenon was about one minute.

THE meeting of German anthropologists took place at Kiel on the 12th, 13th, and 14th inst., and was well attended. Strassburg was chosen as the meeting-place for next year. Prof. Schaaffhausen of Bonn presided, and addresses were delivered by Professors Handelmann, Mehlis, Fraas, Virchow, Ranke, Stieda, and others. On August 14 an excursion was made to Lübeck. The Schleswig-Holstein Anthropological Society had arranged an interesting exhibition for the occasion.

THE British Archæological Association concluded a very successful meeting at Wisbeach on Saturday. Under the presidency of the Bishop of St. David's, the Cambrian Archæological Association held its annual gathering at Lampeter last week.

A CANTON correspondent, under date April 12, sends us the following account of the tornado of April 11 :—Yesterday afternoon, April 11, Canton was visited by a whirlwind of terrific force and unparalleled destructiveness. There was a thunderstorm from 2 P.M. to 3.30; when this was over, lumps of ice, about the size of pigeons' eggs, but shaped like the star-fish, fell in great quantities. Our surprise was hardly over at this strange phenomenon (thermometer 80° F. in the shade) when a noise was heard, like that made by the screw of a ship as a person on board sleeping close to it would hear it, rising and falling in regular rhythm. This sound was occasioned by the travelling of a wind of an intensity that baffles description, which burst upon the city and settlement, scathing and blasting everything which came within its fell grasp. For a space of time, variously estimated at from three to five minutes, it performed its work of destruction, uprooting trees, unroofing houses, overturning walls, engulfing boats, and leaving behind a scene of desolation such as only an eye-witness would believe in. The path along which the tornado passed was converted into shapeless ruins, but fortunately its width was not more than 200 yards. In Shamien (the foreign settlement) 134 large banyans, some of eighteen years' growth, have been blown down, most of them torn up by the roots, and in rare cases the trunks have been rudely snapped in two. A large banyan, distant twenty yards from our house, was torn up and hurled roots foremost, right into the verandah, smashing to chips the solid stone balustrade. One single instance will give you a fair idea of the force of this hurricane. A tile was found sticking in the side of a tree (in the Consulate grounds), into which it had penetrated two inches. A coolie was killed on the road fifty yards from our house by a brick blown away. Men were blown yards into the air and killed, and in one instance, a cow was blown up, but was not killed. The stone seats in the Bund, and stones over a ton weight have been driven yards away. The immense granite blocks forming the parapets of the bridge were hurled bodily into the canal. The track followed by the tornado through the native city is marked by a confused mass of bricks and mortar, and in some places there is literally "not left one stone standing on another." According to a native estimate the number of houses entirely destroyed is about 5,000, the total damage to *foreign* houses about 12,000*l.* sterling, and the loss of life 6,000. Already 4,000 corpses have been interred, and more are being dug up every minute.

WE have received the first part (*Polypetalæ*) of a "Diagnoses Plantarum Novarum vel minus Cognitarum Mexicanarum et Centrali-Americanarum," by Mr. W. B. Hemsley. This, we believe, is merely the forerunner of a work of great extent and importance which Mr. Hemsley has undertaken, of the scope of which the following statement may give some idea. It may be known to some of our readers that Messrs. Godman and Salvin, aided by various specialists, have for many years been engaged in working up the zoology of Central America and Mexico. About three years ago it occurred to them that it would add greatly to the interest of their work if the botany could be so far worked

up as to determine the general laws of distribution for comparison with those obtaining in the animal kingdom. After some consultation with Sir J. D. Hooker, and other botanists, it was decided to make the Kew herbarium the basis of an enumeration of all the plants hitherto found in the countries lying between Panama and the territories of the United States. The principal reason that led to this decision was the fact that the vast collections at Kew have recently been carefully studied for Messrs. Bentham and Hooker's "Genera Plantarum," and for various other publications, so that as far as generic types are concerned, Kew herbarium is perfectly available and reliable for the object in view. To this will be added all the species published, but not represented at Kew by named specimens, and the novelties contained in the collections made by the French Scientific Commission. The enumeration will be supplemented by references, localities, altitudes, and everything that will be useful in drawing up an essay on the distribution, &c., of the plants. Although it was impossible to undertake a critical examination of all the species, a considerable number of interesting and apparently new species will be described, and many of them figured, from drawings by Fitch, and coloured drawings done on the spot by Mrs. Salvin.

THE valuable collection made by the Brothers von Schlagintweit during their extensive journeys through India and Thibet is now arranged for exhibition in the royal castle at Nuremberg. It forms one of the most extensive collections ever brought from the East, and possesses objects of rare value, especially for anthropology. Among these might be mentioned the plastic representations of Indian races, numbering 275 specimens, prepared from casts taken from living individuals, and carefully arranged according to castes and races. A large variety of skulls from different regions in India will also prove of no small use to the growing number of students of cranial development.

WE notice the death at Paris of M. J. Fordos, a well-known French chemist, and vice-president of the Paris Chemical Society. His name is chiefly known in connection with researches on thio-acids, and numerous derivatives of sulphur, ligneous colouring matters, estimation of morphium, and several technical subjects, especially the manufacture of cyanides and ferro-cyanides.

PROF. SUESS, the well-known Vienna geologist, is at present traversing Italy with a number of his students, engaged in a geological study of the peninsula. The journey includes Vesuvius and Etna.

THE additions to the Zoological Society's Gardens during the past week include a Prairie Wolf (*Canis latrans*) from the Rocky Mountains, North America, presented by Prof. M. C. Vincent, F.G.S., F.R.G.S.; a Common Jackal (*Canis aureus*) from India, presented by Mr. J. Smith; a Spotted Ichneumon (*Herpestes auropunctatus*) from Nepal, presented by Mr. W. Pyne; a Bronze Fruit Pigeon (*Carpophaga ænea*) from India, presented by Mr. A. H. Jamrach; a White-eared Bulbul (*Pycnonotus leucotis*) from North-West India, presented by Mr. W. Woolner; a Black Saki (*Pithecia satanas*) from the Lower Amazons, deposited.

THE BRITISH ASSOCIATION

REPORTS.

Report of the Committee for Commencing Secular Experiments on the Elasticity of Wires, by J. T. Bottomley.—The Committee have to report that the arrangements for suspending the wires for secular experiments on elasticity are now complete, and that within the last few days two wires, one of palladium and the other of platinum, have been suspended in their places.

An iron tube has been erected in one of the rooms in the tower of the University Buildings in Glasgow. It is 60 feet long, 9 inches wide, and 4½ inches deep from face to back. It is of rectangular section, in lengths of 6 feet, and it is supported by being firmly attached to the heavy outer stone wall of the tower.

At the top of the tube there is a heavy gun-metal plate which is supported independently of the iron tube; and from this plate the wires under examination are to be suspended, as well as additional wires to be used for carrying additional comparison marks. With this arrangement no yielding of the supporting plate that may take place will introduce errors into the results of measurement of the lengths of the wires; for the point of support of the wire carrying comparison marks will experience the same amount of lowering, due to the yielding, as is experienced by the wire to be measured against these marks. The gun-metal plate has been pierced with three rows of holes, through which the wires are to pass. The holes are trumpeted at each end, so as to avoid sharp contact with the wires; and the rows are arranged so that the wires shall hang down in their planes parallel to the face of the tube. It has not yet been decided what is the best way of fixing the upper ends of the wires above the gun-metal plate, or of attaching the weights to their lower ends. No thoroughly satisfactory mode of attachment has yet been found. In the course of experiments to be referred to immediately, which have been carried on at Glasgow on the breaking weight, and the Young's Modulus of Elasticity of the gold, platinum, and palladium wires, which, it is intended, shall be first suspended for examination, several modes of suspension have been tried; but it has not been found possible to make sure of avoiding very considerable weakening of the wire at the points of attachment at the ends.

At the bottom of the iron tube there is a window of plate glass through which the lower parts of the wires can be viewed, and the window can be drawn up so as to allow of the lower parts of the wires being reached.

In front of the window a strong gun-metal table is set up. It is supported independently of the iron tube and of the floor of the room, on iron brackets fixed to the stone wall of the chamber, and is very carefully levelled. On this table a cathetometer is carried, by means of which marks on the wires are to be observed. The cathetometer moves on the table parallel to the planes of the rows of wires. It has the two back feet of the triangular sole plate on which it is supported movable in a V-groove cut in the table, the third foot resting on the plane upper surface. There is also a slot cut in the table through which a screw passes up from below to the sole plate of the cathetometer, and by means of this screw the cathetometer can be clamped in any required place.

The cathetometer is a small instrument which has been constructed by Mr. James White of Glasgow for the purpose of these experiments. The main pillar is one foot high. It is supported on a sole plate having three levelling screws. The telescope or microscope, having cross-fibres, is raised or lowered on this pillar on a proper geometrical slide, and has also a lifting screw in connection with a vernier for giving fine adjustment. The vertical pillar is carefully graduated; and by means of this scale the differences of levels of proper marks put upon the wires are to be determined.

The arrangements have only been completed within the last few days. They require to be carefully tested in several points, and particularly the cathetometer requires careful examination. There is every reason, however, to expect that the work will turn out quite satisfactory. As soon as possible the work of testing will be completed and wires suspended, measured and marked.

During the past year experiments in connection with this investigation have been carried on in the laboratory of the University of Glasgow on the breaking weights and elastic properties of various wires. In the first place the breaking weights and the Young's modulus, or modulus of elasticity for longitudinal pull, have been determined for the gold, platinum, and palladium wire with which it is proposed that the secular experiments on elasticity shall commence. A large number of experiments on the effect of stress, maintained for a considerable time, in altering the breaking weight and the extension under increased stress of various wires, have been carried on. Soft iron wire, steel wire, and tin wire in particular, have been experimented upon, and already some interesting results have been obtained, showing that prolonged application of stress certainly produces a noticeable effect.

Numbers showing the nature of the results already arrived at are appended; but the whole subject still requires much careful examination.

Report of the Committee consisting of James R. Napier, F.R.S., Sir W. Thompson, F.R.S., W. Froude, F.R.S., J. T. Bottomley, and Osborne Reynolds, F.R.S., Sec., appointed to investigate the effect of Propellers on the Steering of Vessels.—The Committee are now of opinion that the work for which they were originally brought together has been fully accomplished. The importance of the effect of the reversed screw on the action of the rudder has been fully established, as well as the nature of its effect completely ascertained. Also, for two years, the Committee have urged the results of their work upon the attention of the Admiralty and the various marine boards, and although they regret that, as yet, they have failed to obtain that general recognition of the facts brought to light which their vital importance demands, they consider that this will surely follow, and that as a Committee they can do no more than publish the reports of the trials and the conclusions to which they have been led.

The following is a summary of the conclusions which have been established, and it is interesting to notice that the conclusions drawn by Prof. Reynolds from experiments on models, have been fully confirmed by the experiments on full-sized ships.

Summary of the Results of the Trials of the Effect of the Reversed Screw on the Steering during the Time a Vessel is stopping Herself.

It appears, both from the experiments made by the Committee and from other evidence, that the distance required by a screw steamer to bring herself to rest from full speed by the reversal of her screw, is independent or nearly so of the power of the engines, but depends on the size and build of the ship, and generally lies between four and six times the ship's length. It is to be borne in mind that it is to the behaviour of the ship during this interval that the following remarks apply:—

The main point the Committee have had in view has been to ascertain how far the reversing of the screw, in order to stop a ship, did or did not interfere with the action of the rudder during the interval of stopping, and it is as regards this point that the most important light has been thrown on the question of handling ships. It is found an invariable rule that, during the interval in which a ship is stopping herself by the reversal of her screw, the rudder produces none of its usual effects to turn the ship, but that, under these circumstances, the effect of the rudder, such as it is, is to turn the ship in the opposite direction from that in which she would turn if the screw were going ahead. The magnitude of this reverse effect of the rudder is always feeble, and is different for different ships, and even for the same ship under different conditions of loading.

It also appears from the trials, that, owing to the feeble influence of the rudder over the ship during the interval in which she is stopping, she is then at the mercy of any other influences that may act upon her. Thus the wind, which always exerts an influence to turn the stem (or forward end) of the ship into the wind, but which influence is usually well under control of the rudder, may, when the screw is reversed, become paramount, and cause the ship to turn in a direction the very opposite of that which is desired. Also, the reversed screw will exercise an influence, which increases as the ship's way is diminished, to turn the ship to starboard or port, according as it is right or left-handed; this being particularly the case when the ships are in light draught.

These several influences, the reversed effect of the rudder, the effect of the wind, and the action of the screw, will determine the course the ship takes during the interval of stopping. They may balance, in which case the ship will go straight on: or any one of the three may predominate, and determine the course of the ship.

The utmost effect of these influences when they all act in conjunction, as when the screw is right-handed, the helm starboarded, and the wind on the starboard side is small as compared with the influence of the rudder as it acts when the ship is steaming ahead. In no instance has a ship tried by the Committee been able to turn with the screw reversed on a circle of less than double the radius of that on which she would turn when steaming ahead. So that even if those in charge could govern the direction in which the ship will turn while stopping she turns but slowly, whereas, in point of fact, those in charge have little or no control over this direction, and unless they are exceptionally well acquainted with their ship they will be unable even to predict the direction.

It is easy to see, therefore, that if on approaching danger the screw be reversed, all idea of turning the ship out of the way of the danger must be abandoned. She may turn a little, and those in charge may know in which direction she will turn, or may even, by using the rudder in an inverse manner, be able to influence this direction, but the amount of turning must be small, and the direction very uncertain. The question, therefore, as to the advisability of reversing the screw is simply a question as to whether the danger may be better avoided by stopping or by turning. A ship cannot do both with any certainty.

Which of these two courses it is better to follow must depend on the particular circumstances of each particular case, but the following considerations would appear to show that when the helm is under sufficient command there can seldom be any doubt.

A screw steamship when at full speed requires five lengths, more or less, in which to stop herself; whereas, by using her rudder and steaming on at full speed ahead, she should be able to turn herself through a quadrant without having advanced five lengths in her original direction. That is to say, a ship can turn a circle of not greater radius than four lengths, more or less (see Hankow, Valetta, Barge),[1] so that, even if running at full speed directly on to a straight coast, she should be able to save herself by steaming on ahead and using her rudder after she is too near to save herself by stopping; and any obliquity in the direction of approach or any limit to the breadth of the object ahead is all to the advantage of turning, but not at all to the advantage of stopping.

There is one consideration, however, with regard to the question of stopping or turning which must, according to the present custom, often have weight, although there can be but one opinion as to the viciousness of this custom. This consideration is the utter inability of the officers in charge to make any rapid use of their rudder so long as their engines are kept on ahead. It is no uncommon thing for the largest ships to be steered by as few as two men; and the mere fact of the wheel being so arranged that two men have command of the rudder renders so many turns of the wheel necessary to bring the rudder over that, even where ready help is at hand, it takes a long time to turn the wheel round and round so as to put a large angle on the rudder.

The result is, that it is often one or two minutes after the order is heard before there is any large angle on the rudder, and of course, under these circumstances, it is absurd to talk of making use of the turning qualities of a ship in case of emergency. The power available to turn the rudder should be proportional to the tonnage of the vessel, and there is no mechanical reason why the rudder of the largest vessel should not be brought hard over in less than fifteen seconds from the time the order is given. Had those in charge of steamships efficient control over their rudders, it is probable that much less would be heard of the reversing of the engines in cases of imminent danger.

Report of the Committee on the best Means of Developing Light from Coal Gas. Read by Mr. T. Wills.—This first part of the report was by Dr. Wallace, and referred to cannel gas, the standard quality of which was assumed to be twenty-six candles. That was the quality delivered by most of the Scottish gas companies, while in London the illuminating power was sixteen candles; in Liverpool, Manchester, and Carlisle, twenty candles; and in most of the other cities in England and Ireland about fourteen candles. The report was largely occupied by a tabulated series of results obtained with different kinds of burners, such as the rat-tail, onion or fish-tail, batwing, and argand, and also the influence of globes of different sizes, shapes, and materials. The report was strongly in favour of cannel rather than common gas, on account of its comparatively small influence on the atmosphere of apartments and the smaller proportion of sulphur it contained. The report also advocated the burning of gas at a comparatively low pressure, and the use of district governors to equalise the pressure in different levels of towns, and of regulators in houses and street lamps, to give the exact pressure calculated to give the best photometric results.

Fourteenth Report of the Committee for Exploring Kent's Cavern, Devonshire. (Abstract.)

The Tortuous Gallery.—When their thirteenth report was drawn, at the end of July, 1877, the Committee had completed the exploration of the "Tortuous Gallery," with the exception of the portions of it termed the "Terminal Chamber" and the "Recess." On entering the Chamber its floor was found to be a complete pavement of blocks of limestone, the removal of which disclosed an almost horizontal bed of the typical breccia —the most ancient deposit yet found in the cavern. It was excavated to the customary depth of four feet, but without reach-

[1] B.A. Reports, 1876-77.

ing its base anywhere. The Chamber measured thirty feet from north to south, from seven to thirteen feet from east to west, and about the same in height. The only objects met with were four pieces of bone and a large lump of oxide of manganese. The Recess yielded twelve teeth of bear and several pieces of bone.

The Undervault.—On the completion of the "Tortuous Gallery" the exploration of an adjacent branch of the cavern, called the "Undervault," was begun. The deposit found in it must be regarded as an uncertain admixture of breccia and the less ancient cave-earth, washed confusedly together. In it were found forty-seven teeth of bear, thirty-three of hyæna, two of fox, numerous bones and fragments of bone, one chert flake, and the greater portion of a large quartzite pebble. Many of the teeth of both bear and hyæna were in jaws and portions of jaws, and some of them were remarkably fine specimens.

The Great Oven.—That branch of the cavern termed the "Great Oven" was partly explored in 1875, but its "Eastern Reach" was then left intact. This reach occupied the Committee from December 18, 1877, to February 15, 1878. It was thirty-four feet long, and varied in width from ten to three feet. The deposits were, in descending order, (1) granular stalagmite, a few inches thick only; (2) cave-earth, also but a few inches thick; (3) crystalline stalagmite, from two to three feet thick; and (4) breccia, the base of which was nowhere reached. The following specimens were exhumed:—Twenty teeth of bear, eight of hyæna, and three of fox, in the cave-earth; one tooth of bear, in the crystalline stalagmite; and fifteen teeth of bear in the breccia. The relics of hyæna were accompanied by a few coprolites.

The High Chamber.—A branch of the cavern, the most remote from the external entrances, has been called the "High Chamber" on account of its suddenly rising several feet above the level of the "Cave of Inscriptions," out of which it opens. Its exploration was commenced in February, 1878, and is still in progress. Up to the end of July it had yielded fifty-three "finds," including eighty-nine teeth of bear, numerous bones and pieces of bone, a chert implement, two chert flakes, and a quartzite pebble, all found in the breccia. There are reasons for believing that this chamber will lead to an entrance of the cavern hitherto unknown.

The president proposed a vote of thanks to Mr. Pengelly. With regard to the quartzite pebble found in the high chamber it appeared to be a block from which a fragment had been separated for some useful purposes. The flint implements are altered, and coated with a white soft substance, some of its original substance having been removed by water.

Prof. Boyd Dawkins said the exploration was a great feat of engineering. He objected to the term quaternary as some times applied to these deposits. The tertiary, quaternary, and pleistocene periods are so closely twined that separation is impossible. He accounted for the arrangement of the animal remains by alternations of climate. In some caves they found generally Arctic animals like the reindeer and glutton associated with animals that were now only found in warm climates, and the probable cause was that there was a great stretch of land over the greater part of the Mediterranean area, from the north of Africa over the region of Europe, until it finally reached Great Britain, and even Ireland. This would afford a means of migration to animals northward and southward, according to the season. This was also shown by the Pyrenees, and so on through Germany, until they arrived at this country. In the Derbyshire caves, Cresswell Cave, for instance, there was a sequence of events very much the same as in this cave. He was now of opinion that the *Machairodus* was a late cave animal, being found in upper cave earth of Cresswell Cave, as well as in Kent's Hole.

Mr. Pengelly was glad to hear Prof. Boyd Dawkins' recantation as to *Machairodus*.

Mr. Plunket read a *Report of the Committee* (secretary, Prof. A. Macalister, M.D.) *on the Fermanagh Caves*, and exhibited a number of animal remains, &c., collected in them.

Prof. Leith Adams said they could not come to any conclusion yet as to the animal remains, for they had not been examined. From what they knew of the extinct animals of these islands, they must come to the conclusion that there was a land connection between England and Ireland.

Prof. Boyd Dawkins said he had looked at the bones, and he found the remains of a domestic hog, shorthorn ox, goat, and red deer—animals which had been used for food—and the bone of a large dog, probably the large deerhound of the sixteenth and seventeenth centuries.

The fourth *Report of the Underground Water Committee* was read by Mr. C. E. De Rance, F.G.S., Assoc. Inst. C.E.—The value of the Government geological maps as a basis for investigation in questions of water-supply was acknowledged; and the areas occupied by permeable formations capable of yielding water in wells sunk in suitable situations was stated to be no less than 26,687 square miles. This, receiving a rainfall averaging thirty inches a year, would yield up to wells not less than six to fifteen inches per annum, or a daily quantity of not less than 240,000 gallons for each square mile of surface, a total quantity far in excess of that required by the population of England or Wales. The great value of the supplies for the towns and districts of the Midland Counties was insisted on because of their purity, and from the unlikelihood of such prospects of water-supply from such sources being stopped by the strong parliamentary opposition which is brought to bear against all large gravitation schemes, whether the water be proposed to be taken from natural lakes, as the Thirlmere for Manchester, or from natural reservoirs as was proposed in the case of Liverpool.

The well borings at Bootle, near Liverpool, of 26 inches diameter just completed for the Liverpool Corporation by Messrs. Mather and Platt, were described as of great interest, the boring having reached a depth of 1,000 feet without reaching the base of the new red sandstone.

The Committee expresses a hope that the boring will be continued, as it may settle several questions not merely of local interest but of national importance: the water-bearing capabilities of the lower beds of the new red sandstone at great depths, the character of the coal-measures which undoubtedly underlie Liverpool, and the depth to them.

Amongst a large number of wells and borings alluded to in the Report was one at Burford, near Witney, in Oxfordshire, where the coal-measures with a coal-seam were found under the ooliths and triassic strata. Then water was also described as being present in the new boring of the Metropolitan Board of Works at Crossness.

Report on the Proposed Kentish Exploration, by R. A. C. Godwin-Austen, F.R.S.—During the past year nothing has been done to warrant an application for any portion of the grant at the disposal of the Kentish boring exploration, but results have been arrived at by private enterprises which indicate the information sought for—whether the palæozoic rocks underlie the chalk formation of the south-east of England as in Belgium and the south of France.

The finding of characteristic upper Devonian fossils in the boring at the corner of Tottenham Court Road and Oxford Street, seems to prove the supposition of the Coal Commission of 1871, that the line of the Thames Valley is that of the course of the palæozoic rocks.

One point remains. In what direction from the end of Tottenham Court Road may the mountain limestone and the coal measures be looked for? That their existence may be certainly inferred is shown by our acquaintance with the physical and geological history of the European area at those early times.

The so-called "Devonian" is but an early stage of the "mountain limestone series," consisting of (1) lower carboniferous or Devonian; (2) carboniferous limestone proper; (3) coal measures.

The Devonian beds, dipping at a high angle, is important; had they been lying flat, it might be inferred that the upper series were denuded, but there is every prospect that these beds may be found underlying the Devonian at some distance from the present bore-hole.

The Tottenham Court Road boring suggests that the Franco-Belgian palæozoic band with which their coal is associated, is continued under London, and within the very narrow limits here assigned (between Oxford Street and the Thames). Considering the vast importance of the discovery of productive coal-measures from the south-east of England westwards, the time has come when the results so nearly arrived at at Tottenham Court Road should be completed. Half the money spent on the Wealden boring at Netherfield would have settled the theoretical question, and even if they were of the same quality as the *Boulonnais* coal, the objections against the quality of that coal have been fully answered.

Major-Gen. Lane Fox, F.R.S., read the *Report of the Earth-*

works Committee: being an Account of Excavations in Cæsar's Camp, Folkestone, and also a paper on *Excavations at Mount Caburn, Lewes, Sussex.*—On Mount Caburn a large number of pits were dug. They were found to contain iron implements and arms entirely of a late Celtic type, and pottery of three descriptions. The fact of these being of a late Celtic type was proved by the getting of the specimens after a considerable amount of digging, and the finding of British tin coins, which were extremely rare, and which were known to be of a late Celtic type. Then excavations were made through the rampart in order to ascertain by means of relics found on the old surface-land what was the date of the first Roman camp. In the upper rampart a quantity of British pottery was found, showing the probability that it was erected at an early time. In the outer rampart pottery of a superior quality was found, by which means it appeared likely that the camp was first erected during the early British period, and was occupied up to the late Celtic period. Subsequently the adjoining camp of Ranscombe was cut through, and Samian pottery was found in the interior, showing that it had been occupied by the Romans; but in the body of the work nothing but British pottery was found, which proves that, though occupied by the Romans, it was not constructed by them. The Ranscombe Camp may, therefore, have been utilised by the Romans, as suggested by Horsfield a long time ago, during an attack upon Mount Caburn. As to Cæsar's Camp, it was ascertained that the whole of the relics found in the body of the several ramparts were of the Norman period, nothing Roman or earlier having been found anywhere.

Report of Committee, consisting of Prof. Harkness and Mr. William Jolly, on the Fossils of the North-West Highlands of Scotland, by Mr. W. Jolly, H.M.I.S., Secretary.—Since the last report one of the most active members of the Committee, the late Dr. James Bryce, has perished in the prosecution of his favourite science. For several years the Committee have explored the great limestone band running from Durness and Loch Eribol to Loch Kishorn, opposite Skye. The fossils discovered were obtained almost entirely from the Durness limestone, fourteen miles east of Cape Wrath, the only other place where they have been obtained in the limestone being at Inchnadamph, or Loch Assynt, in the west of Sutherland. The considerable collection of fossils made was placed in Dr. Bryce's care, but, on his unexpected decease, his collection was found to be more or less scattered and unmarked, and the Committee have as yet been unable to discover the Durness fossils, although careful search and inquiries have been made; they hope to be able to report their discovery to the next meeting.

Through the good offices of several friends, and particularly the Rev. W. C. Grant, a considerable collection has been made from Garveilan, near Cape Wrath, while in the quartzites of Lough Eribol numerous worm or annelid borings have been obtained, and Mr. Mackay has this year discovered hitherto undescribed fossil remains in the same quartzite. It is proposed to have these carefully examined, and to endeavour to ascertain their bearing on the general problem of the place and succession of rocks of the North-West Highlands.

The Committee consider it desirable they should be reappointed, with a grant at their disposal to prosecute their search for fossils, and also to examine and report on those already obtained.

SECTION A.—MATHEMATICAL AND PHYSICAL.

A New Determination of the Number of Electrostatic Units in the Electromagnetic Unit. (Telegram and letter to Sir William Thomson from Prof. W. E. Ayrton.)

The Red Sea, August 3, 1878

From Singapore I sent you the following telegram on July 13. "Kindly inform British Association that air-condenser measured magnetically and statically gives mean value ratio of these units (29·80) twenty-nine point eight nought ohms.; Foucault's velocity light."

In the autumn of this year I propose communicating a full account of this investigation to the Physical Society or the Society of Telegraph Engineers, or otherwise as you may advise; but I thought that as the British Association Committee had for so long busied itself with the determination of electrical units you might deem the result of this investigation of Mr. Perry and myself worthy of a preliminary notice at the meeting of this Association to be held this year at Dublin. Not being sure that I should arrive in Europe in time to reach Dublin at the commencement of the meeting, although I hope to be present during the last three or four days, I took the liberty of sending you the telegram quoted above.

The result we have obtained for "v" is the more interesting inasmuch as without any bias being given to any one of our experiments, the mean value is identically the same as that obtained by M. Foucault for the velocity of light, whereas all previous determinations of the number of electrostatic units in an electromagnetic unit have led to results differing considerably from Foucault's velocity.

It appeared to Mr. Perry and myself that the method best suited for the accurate determination of v consisted in measuring the capacity of an air-condenser (1), electromagnetically by the swing of the needle of a ballistic galvanometer; and (2) electrostatically by a measurement of the linear dimensions of the condenser, since the equation connecting these capacities

$$s = v^2 S$$

s being the absolute electrostatic capacity,
S ,, electromagnetic ,,

leads to an equation involving only the *square root* of a resistance.

Two difficulties of course presented themselves in this investigation, difficulties that it took us many months to overcome, labouring as we were under the disadvantage of experimenting in a country like Japan. They were—

(1) To obtain a large air-condenser of which the plates had sufficiently true surfaces that the electrostatic capacity could be accurately measured; at any rate when the plates were not nearer than half a centimetre to one another.

(2) To obtain a galvanometric arrangement of sufficient sensibility to measure the small capacity of such an air condenser and sufficiently ballistic that the air damping should be almost inappreciable.

A full description of the condenser we employed (and which had a guard ring, and all the different arrangements we could think of for obtaining accurate results) will accompany the account of the investigation to which I have referred. It is sufficient here to mention that the errors arising from the surfaces of the condenser plates not being true planes were practically eliminated by capacity experiments being made with successive adjustments of the condenser plates, a different set of points in the upper plate being each time brought to the fixed distance from the lower plate.

The arrangement of a ballistic galvanometer to fulfil the two conditions mentioned in (2) was very troublesome. I made several astatic needles none of which satisfied us, and we were beginning to fear my departure from Japan would necessitate the abandoning of the investigation. At last, however, an astatic combination containing forty small magnets (and of which a description will accompany the paper), gave satisfactory results, and I obtained three excellent sets of observations on June 18, June 23, and June 25, when my departure put an end to further investigation. The *mean* values obtained for "v" on each of these three days were—

29·74 ohms,	June	18
29·95 ,,	,,	23
29·72 ,,	,,	25

Final mean 29·80

It will be observed that the greatest difference between any one of the three daily means and the final mean, is only about half per cent. The final mean 298·0 million metres per second (and which represents the mean of ninety-eight discharges of the air-condenser) may, I think, be regarded as correct to, at any rate one per cent, and is exactly equal to M. Foucault's velocity of light.

In the astatic combinations I employed prior to June 18 I used eight needles, and weighted the lower set of needles with pieces of brass, so as to give it a barrel shape, but the results were unsatisfactory, as there was either not sufficient delicacy or else too much damping. Consequently all the numbers obtained prior to June 18 have been abandoned. On June 18 were

made the first set of experiments with the forty-magnet astatic combination, the idea of this arrangement being to make an approximately spherical mass of little magnets all slightly separated from one another, and all previously magnetised to saturation. As it would have been too difficult to make this entire sphere all of magnets I finished it off with segments cut from a little wooden sphere. But the half Napierian logarithmic decrement was 0·12095, and we thought this too high. Consequently, in the interval from June 18 to June 23, I took this astatic combination down, and replaced the segments of the wooden sphere by segments of a small leaden hemispherical *shell*. This diminished the half Napierian logarithmic decrement to 0·07825, and with a periodic time of 39·5 seconds I obtained most consistent results. But on the other hand the close agreement of the results obtained on June 18 and on June 25 leads one to conclude that the wooden segments were quite satisfactory, and that replacing them with the leaden shell was unnecessary.

The table at the end of this letter gives the value of the most important constants employed. The battery consisted of 382 perfectly new Daniell's cells in series, and the galvanometer had a resistance of 20,000 ohms. All resistances were compared with a new German silver wire box recently received from Messrs. Elliott, London.

The values obtained for v are (as far as I am aware) up to the present time as follows:—

MM. Weber and Kohlrausch	31·074	ohms.
Sir W. Thomson	28·2	,,
Prof. Clerk Maxwell	28·8	,,
Professors Ayrton and Perry	29·80	,,
Velocity of light, M. Foucault	29·8	,,

During the last twelve months we have been hard at work with the determination of the electromotive force of contact of metals and liquids, using a new apparatus. Some of the results are, we venture to think, most interesting—for instance, the electromotive force of contact of hot and cold mercury, *no other conductors being in contact with either mercury*; the electromotive force of contact of a cold metal and hot mercury, no third conductor being in contact with either, &c. The determination of the electromotive force of contact of the pairs of constituents of Mr. Latimer Clark's constant mercurous sulphate cell was most laborious, and occupied me weeks, in consequence of the difference of potential that exists between the body of the mercurous sulphate paste, and the layer of water that floats on the surface. However, a forlorn hope kept me hard at it, and I am glad to say at last I was successful in getting good results. We have gone over all the old ground that furnished the basis of our former paper, as well as much new ground.

Determination of the Number of Electrostatic Units in an Electromagnetic one.

Date.	Area of condenser plate in square centimetres.	Distance between the plates in centimetres.	Weight of the astatic combination in grammes.	Periodic time in seconds.	Half the Naperian logarithmic decrement.	Mean value of v.	Remarks.
June 18	1324·96	1·024	2·15	25·3	0·12095	29·74	Ninety-eight discharges of the air-condenser.
,, 23	1323·14	0·7728	3·4	39·5	0·07825	29·95	
,, 25	1323·14	0·7728	3·4	42·2	0·081865	29·72	

The distance between the upper condenser plate and the guard ring was slightly increased by diminishing the size of the plate to avoid the possibility of loss of electricity.

June 18.—The lower set of needles was weighted with segments cut from a small wooden sphere.

June 23 and after.—The lower set of needles was weighted with segments cut from a small leaden spherical shell.

Number of magnets in astatic combination 40.

Number of new Daniell's cells in series 382.

General Results of some Recent Experiments upon the Coefficient of Friction between Surfaces moving at High Velocities, by Douglas Galton, C.B., D.C.L., F.R.S., &c.—The author of this paper has been recently engaged in making some experiments upon the coefficient of friction when the surfaces in contact move at high velocities, in connection with the action of brakes in use on railways; and the results which have been arrived at appear to present some interesting features in respect of the laws which govern the coefficient of friction.

The experiments were made to ascertain the friction between the brake blocks and the wheels of a railway carriage.

The levers which move the brake blocks were fitted with dynamometers to show first the pressure which was applied to force the blocks against the wheel, and secondly, the force or tangential strain exerted between the wheel and the block when the latter is pressed against the wheel. The dynamometers used were adaptations of Richards's indicators which act by water pressure which transfers the pressure to cylinders fitted with pistons to which a pencil is attached, so as to register the pressure over a travelling sheet of paper, as is used with steam indicator diagrams. A dynamometer on a similar principle was attached to the draw bar so as to register the force exerted during the experiment in drawing the carriage.

The speed was also recorded on diagrams by means of the Westinghouse speed indicator, which also acts by water pressure and depends for its action on the speed of revolution of the axles.

The carriage or van fitted with the apparatus had two pairs of wheels; one pair of wheels was fitted with brakes whilst the other pair was free. A speed indicator was attached to each pair of wheels, so that the speed of the carriage could be ascertained at any time independently of the speed of the braked wheels.

To check the Westinghouse speed indicator two of Stroudley's speed indicators were also attached to the van, but these do not register automatically. The distribution of the weight of the van between the two pairs of wheels was obtained, as well as the weight of the wheels and axles themselves; and in order to ascertain the weight thrown on the braked wheels during the progress of the experiment, a dynamometer fitted to the springs of the van showed the weight at every moment carried on the unbraked wheels, from which information it was easy to deduce the weight on the braked wheels.

The apparatus was designed by Mr. Westinghouse, and constructed under his supervision by the Brighton Railway Company, through whose assistance these experiments were carried into effect.

The effect of applying the brake to the wheels is twofold. So long as the wheels to which brakes are applied continue to revolve at the rate of rotation due to the forward movement of the train, the effect of the blocks is to create retardation by the friction between the block and the wheel; but when the pressure applied to the blocks causes the friction to exceed the adhesion between the wheels and rail, the rotation of the wheels is arrested, and the wheel becomes fixed and slides on the rail, being held in its fixed position by the brake blocks.

Therefore the experiments give the coefficient of friction—1, between the brake blocks and the wheel, which is equal to

$$\frac{\text{the tangential force}}{\text{the pressure applied}};$$

2, between the wheel and the rail, which is the

$$\frac{\text{friction of the brake blocks}}{\text{weight upon the wheels}}.$$

It has been generally stated that there is no difference in the coefficient of friction observed in the case of bodies at rest, *i.e.*, in a condition of static friction, and the coefficient of friction in the case of moving bodies, *i.e.*, in a condition of kinetic friction; but Mr. Fleeming Jenkin, in his paper read before the Royal Society in April, 1877, upon the friction between surfaces moving at very low speeds, alludes to the fact that in all cases where a difference in the coefficient of friction is observed between static and kinetic friction, the static friction exceeds the kinetic.

Coulomb also points out, in his experiments that in the case of static friction, the coefficient of friction increased with the time during which the bodies had been at rest.

The experiments of Coulomb, Rennie, Morin, and Jenkin, were made with bodies moving at comparatively low velocities.

The following table shows the mean results obtained from a large number of the experiments made with the apparatus above described, upon the action between the cast-iron brake blocks and the wheels fitted with steel tyres:—

Average.		Coefficient of friction between cast-iron brake blocks and steel tyres of wheels.			
Miles per hour.	Feet per second.	At commencement of experiment, *e.g.*, to 3 seconds.	At from 5 to 7 seconds.	At 12 to 16 seconds.	At 24 to 25 seconds.

25	—	·080	·074	—	—
15	—	·087	—	—	—
10	—	·110	—	—	—

The general results of these tables show that the coefficient of friction between moving surfaces varies inversely in a ratio dependent upon the velocity at which the surfaces are moving past each other; probably the expression would be of the form of $\frac{a}{b+v}$.

The coefficient of friction, moreover, at these velocities becomes smaller also after the bodies have been in contact for a short time. That is to say, the longer the time the surfaces are in contact, the smaller apparently does the coefficient of friction become. This result appears more marked in the case of cast-iron blocks than of the wheel sliding on the rail. This effect, however, does not appear to be unnatural, as the friction developes heat, and the consequent expansion tends to close up the pores and to make the heated surface a more united surface than the colder surface; besides which it is probable that, in the act of rubbing, small particles may be detached which may act as rollers between the surfaces.

It will also be observed that the coefficient of friction between the cast-iron block and the steel tyre is much larger than that between the steel tyre of the wheel and the rails, which were also generally of steel. As has been above-mentioned, the sliding of the wheel on the rail takes place when the friction of the brake blocks is greater than the adhesion between the wheel and the rail, which is due to the weight upon the wheel. This was found to amount generally to about 24 to 28 per cent. of the weight. The influence which these results have upon brakes for railway trains may be briefly summed up as follows :—

In order to produce a given result at different velocities the pressure applied to the brake blocks must increase in the proportion shown by the coefficient of friction. Thus at fifty miles an hour the pressure required to make one pair of wheels slide on the rail was nearly 27,000 lbs., whilst at twenty miles an hour a pressure of about 10,300 lbs. was found sufficient to obtain the same result. The strain on the draw-bar showed that the retarding force or the tangential strain between the brake blocks and the wheels followed very nearly the same law of variation; that is to say, in order to produce a degree of friction on the wheel at fifty miles an hour which shall exert a retarding force on the train equal to that at twenty miles an hour the pressure applied to the brake blocks at fifty miles an hour must be nearly $2\frac{1}{2}$ times as great as that required at twenty miles an hour, and a still greater pressure is required for higher velocities. Therefore whilst a comparatively low pressure would make the wheel slide at low velocities, it was difficult to obtain any sufficient pressure to make the wheel slide at velocities over sixty miles an hour.

A satisfactory brake, therefore, should be capable of bringing on a very high pressure almost instantaneously, and then the pressure should be gradually reduced as the train comes to rest.

The figures given in the above tables must at present be accepted as only provisional until an accurate mean has been obtained from the diagrams, which are not yet all worked out. But it may be assumed as an axiom that for high velocities a brake is of comparatively small value unless it can bring to bear a high pressure upon the surface of the tyre almost instantaneously, and it should be so constructed that the pressure can be rednced in proportion as the speed of the train is reduced so as to avoid the sliding of the wheels on the rails.

I must add that these experiments were made upon the London, Brighton, and South Coast Railway, who, through their able general manager, Mr. Knight, and locomotive engineer, Mr. Stroudley, gave every assistance in the construction of the van and the running of the train. The apparatus was mainly devised by Mr. Westinghouse and the experiments were carried on under his immediate supervision. The earlier experiments were also made with the assistance of Mr. Horace Darwin.

SECTION B.—CHEMICAL SCIENCE.

On a Simplification of Graphic Formulæ, by Oliver J. Lodge, D.Sc.—In the graphic formulæ of a compound the elements were ordinarily represented by their chemical symbols (capital letters), and the connection between the atoms was represented by straight lines joining the letters. Graphic formulæ were of most use in organic chemistry, where the principal compounds consisted only of the elements C, H, O, N, whose atomicities were 4, 1, 2, and 3 or 5 respectively. In any formulæ, therefore, four bonds always radiated from the letter C : N was the meeting place of three or five bonds, according to circumstances; two bonds met at each O, and a single bond terminated at every H. Supposing that the letters were omitted and the bonds joined together, the position of the atoms would still be apparent as the meeting-place of a definite number of bonds, and therefore the letters were unnecessary. The simplification he proposed, then, was the omission of the usual symbols used to denote the atoms, and the joining of the bonds in such a way as clearly to define the atomicities, and therefore the natures of the several atoms. Formulæ so drawn became reduced to a sort of geometrical diagram, and conversely any geometrical curve represented some real or imaginary chemical compound.

Abstract of a Paper on the Action of Heat upon the Selenate of

Ammonium.—Dr. Edward W. Davy, Professor of Forensic Medicine, Royal College of Surgeons, Ireland, read, on behalf of his colleague, Dr. Charles A. Cameron and himself, a paper containing the results of some observations which they had conjointly made on the action of heat upon the selenate of ammonium, from which they have shown that, when that salt is exposed to heat, it first resolves itself into ammonia and an acid selenate of ammonium (a hitherto undescribed salt), and that this latter, on the application of a higher temperature, breaks itself up into water, selenium, selenious anhydride, and nitrogen, thus showing that in the first stage of the decomposition of this selenate by heat it resembles the sulphate of ammonium in furnishing an acid salt under the same circumstances, but that in the separation of selenium in the second stage of the process there is no analogy between the sulphate and selenate of ammonium.

Abstract of a paper *On the Action of Chlorine upon the Nitroprussides.*—Dr. Edmund W. Davy read a paper *On the Action of Chlorine upon the Nitroprussides*, an interesting class of compounds obtained by the action of nitric acid on the soluble ferro- or ferri-cyanides, which were first investigated by Dr. Lyon Playfair, several years ago. Dr. Davy has ascertained that the statements which exist in the different standard works on chemistry as to chlorine having no action on those salts, is incorrect, at least as regards several of the nitroprussides which he has made the subject of investigation, for he has found that some of them are immediately, and others, after long exposure, more or less, acted on by that substance, even when they are excluded from the light. When, however, they are subjected to the combined action of chlorine and the sun's rays, they are soon completely decomposed, the principal products being an oil-like matter, which agrees in its properties with the substance known under the name of chlorocyanic oil, ferric chloride, hydrochloric acid, and a chloride of the metallic base of the salt employed.

The following nitroprussides, viz., those of potassium, sodium, barium, calcium, zinc, iron, and silver, were found to be those decomposed when exposed to the action of chlorine and sunlight; and it is probable that other nitroprussides would be similarly affected. The only one of those salts, however, which the author has observed resisting this action is that of copper, which has remained apparently unaffected after some weeks' exposure to its influence.

On the Spectrum of Chlorochromic Anhydride, by Dr. Johnstone Stoney and Prof. Reynolds.—The authors exhibited and described the spectrum produced by the absorption of the vapour of chlorochromic anhydride. This spectrum is of peculiar interest from its having supplied information as to the duration and character of the motion of the molecules of the gas which produce it. The spectrum consists of lines nearly equally spread, but of various intensities. From the position of the lines, of which 105 have been examined, it has been ascertained that they are all to be referred to one motion in the molecules of the gas of which they are all harmonics or quasi-harmonics, and which, on the supposition that they are harmonics, is repeated 810,000,000,000 every second in each molecule, and from the succession of intensities it may be surmised that this motion is in some way related to that of a particular point in a violin string vibrating under the influence of the bow, viz., a point nearly, but not quite, two-fifths of the string from the one end.

On a New Method of Alkalimetry, by Dr. Louis Siebold, F.C.S.—The plan recommended consisted in the reverse application of Liebig's process for estimating hydrocyanic acid, and was based on the fact that the volumetric determination of an alkaline cyanide by means of silver nitrate was in no wise affected by the presence of free hydrocyanic acid. From the volume of silver solution used the quantity of alkali might be as readily calculated as that of the cyanogen. If the applicability of this process for alkalimetric purposes were confined to the estimation of caustic alkalies nobody would, in Dr. Siebold's opinion, think of using it in preference to the process commonly adopted; but he wished to show that it might with great advantage be applied to the determination of alkaline carbonates. From ·5 to one grain of the potassium or sodium carbonate should be dissolved in about 100 c.c. of distilled water, the solution mixed with an excess of hydrocyanic acid (10 to 20 c.c. of acid of Scheele's strength), and then decinormal solution of silver nitrate added from a burette until a permanent opalescence is produced, the reaction occurring according to the following equation:—

$$K_2CO_3 + 2HCy + AgNO_3 = KAgCy_2 + KNO_3 + CO_2.$$

Whereas under ordinary circumstances hydrocyanic acid was incapable of decomposing alkaline carbonates it effected a complete decomposition in the presence of silver nitrate. The mixture did not require boiling, and the whole operation might be performed within a few minutes. If, after the end of the titration, the mixture were boiled, and the addition of decinormal solution of silver nitrate proceeded with, this time using potassium chromate as an indicator, the volume of silver solution required to insure complete precipitation of the silver cyanide would be exactly equal to that used in the first titration. This second reaction might then, if desired, be used as a check on the determination. In the presence of chloride the volume of silver solution used in the second experiment would be greater than that used in the first, the difference between the two being exactly that required to precipitate the chloride. In this manner a determination of the chloride might be readily combined with that of the alkaline carbonate. The following results were quoted to show the accuracy of the process:—

Pure Potassium Carbonate.

On the Estimation of Mineral Oil or Paraffin Wax when mixed with other Oils or Fat.—William Thomson, F.R.S.E., read a paper on this subject. He said that mixed oils were now often used for lubricating purposes, and a common mixture, composed of mineral oil with some animal, vegetable, or fish oils, was now extensively used, and it was an important point to be able by analysis to determine the amount of mineral oil which such mixtures contained, and as he could find no published process to effect this, he devised, after much work, the following, which he found by repeated tests to give very accurate results:—He boiled some of the sample with an alcoholic solution of caustic soda, which converted all the animal, vegetable, or fish oils into soap. This was then mixed with sand, evaporated to dryness on the steam bath, the residue placed in a bottle washed with petroleum spirit, and distilled at a temperature under 190° F. This dissolves out the mineral oil, leaving the soap insoluble. The spirit is now distilled off from the spirit solution of mineral oil in a large flask, and after thus evaporating off the bulk of the spirit, the concentrated solution is transferred to a smaller flask with a hole blown in its side, into which is fitted a cork carrying a thermometer and glass tube; the thermometer should touch the liquid, going nearly to the bottom of the flask. It is placed on a sand bath and heated at a temperature not exceeding 220° F., and dry air blown into the flask through the tube in the cork, to remove the last trace of spirit, and the residue of mineral oil weighed and calculated on the weight of the original mixed oil taken.

On some Double Salts of Glucinum, by Prof. Emerson Reynolds.—This communication contained an account of some investigations upon some compounds of the rare metal glucinum, and demonstrated by several interesting experiments how the author had succeeded in obtaining the metal in a state of purity by the use of the double fluoride of glucinum and potassium. A second salt, double chloride of platinum, and glucinum, had also been prepared in an exceedingly pure crystalline form. Dr. Reynolds stated that he had also made experiments with a view to determine the specific heat of glucinum, which he fixed at ·642, and this multiplied by the probable atomic weight of the metal—namely, 9·2—gave 5·90, a result fairly in accordance with the law of Dulong and Pettit.

Summary of Investigations in the Pyridine Series, by Dr. W. Ramsay.—These bases, which possess the general formula, $C_nH_{2n-5}N$, are tertiary bases. They form an additive product with iodides of alcohol radicles, of which a good example is C_5H_5N, CH_3I, best named pyridine methyl-iodide, as it resembles a salt in its constitution. They are not attacked by nitrous acid, and the cyanate, when heated, undergoes no molecular change, but merely splits up into the base, and the usual polymer of cyanic acid, cyanuric acid.

Picoline, C_6H_7N, on oxidation, yields a dicarbopyridenic acid, $C_7H_5NO_4$, which, on distillation with soda-lime, decomposes into pyridine, C_5H_5N, and carbonic anhydride, $2CO_2$. It has therefore the structural formula $C_5H_3N(2OOH)_2$. Attempts to prepare lutidine, C_7H_9N, from the aldehyde of that acid, as well as by the reaction

$$C_5H_3N(COOCH_3)_2 = C_7H_9N + 2CO_2,$$

failed, owing, in the first instance, to the small yield of aldehydes, and, in the second, to the total decomposition of the product into pyridine, carbonic anhydride, and carbon.

In spite of the failure of these attempts the author regards it as probable that picoline is methyl pyridine; entidine, dimethyl pyridine, from the following consideration:—The amount of heat evolved in the formation of these bases is probably very high. That heat, added to the amount evolved by the combination of the base with an acid, is likely to be greater than the total number of heat-units evolved by the oxidation of the base; hence these bases are unoxidisable in acid solution. But when oxidised in alkaline solution, the amount of heat evolved by oxidation is supplemented by that arising from the combination of the resulting acid with the alkali, and then exceeds the heat evolved during the formation of the base. The presence of nitrogen therefore gives great stability to the molecule, and prevents the methyl groups from being oxidised to carboxyl-groups, as in the case of toluol, xylol, &c. At least three isomeric acids of the general formula $C_7H_5NO_4$ have been discovered, and it is probable that as many as six are capable of existence. These the author has named α, β, and γ, dicarbopyridenic acids. The α-acid is obtained by oxidising picoline or entidine, and the last two from entidine.

An attempt to pass from furfurol to pyridine by the series of reactions—

$C_5H_4O_2$, Furfurol, $C_5H_6O_2$, Furfuryl alcohol, C_5H_5OCl, Furfuryl chloride, $C_5H_5ONH_2$, Furfuryl amine, C_5H_5N, Pyridine,

was unsuccessful, owing to the instability of furfuryl chloride.

From the stability of the pyridine group, and the instability of the furfurol group, the author regards it as probable that the constitution of the former is best represented by a closed, and that of the latter by an open, chain.

On Some of the Derivatives of Furfurol, by Dr. W. Ramsay.—It was found impossible to prepare furfuryl chloride by the action of phosphoric chloride, or of hydrochloric acid gas on furfuryl alcohol, $C_5H_6O_2$, owing to a complete decomposition of the organic matter, with separation of carbon.

Furfurine, prepared by heating furfuramide and possessing the same formula, $C_{15}H_{12}N_2O_3$ unites with methyl iodide, forming the hydriodide of methyl-furfurine; this salt, on treatment with ammonia, deposits the base $C_{15}H_{11}(CH_3)N_2O_3$, as a viscous oil, insoluble in water, but soluble in alcohol. The base again unites with methyl iodide, giving the hydriode of dimethyl furfurine, $C_{15}H_{10}(CH_3)_2N_2O_3HI$, which is also decomposable by ammonia with liberation of the base, dimethyl furfurine $C_{15}H_{10}(CH_3)_2N_2O_3$. This base appears also to be capable of union with methyl iodide.

Furfurine, then, appears to be a secondary base containing two atoms of hydrogen replaceable by methyl. Whether more can be replaced the author was unable to decide, as the loss by repetition of the operation was very considerable.

On the Thetines, by E. A. Letts.—Prof. Letts' experiments were undertaken as a sequel to the research of Prof. Crum Brown and himself, on dimethyl thetine and its compounds, and with a view to the thorough investigation of the thetines as a group—the phenomena attending their formation—the action of heat and oxidising agents on them, and the difference in their properties as the series is ascended. Incidentally Prof. Letts has also studied the action of bromacetic acid on certain sulphides of hydrocarbon radicals and the action of bromacetic and iodacetic ethyl ether on sulphide of methyl.

Notes on Aluminium Alcohols, by Dr. Gladstone and Mr. Tribe.—In 1876 the authors described the joint action of aluminium and iodine on alcohol, and two aluminium ethylates resulting from it. They now showed that a similar reaction takes place with methylic alcohol, especially when the aluminium is rendered more powerful by conjunction with deposited platinum; and that an analogous body is still more readily formed from amylic alcohol. These two substitution-products had not yet been prepared in a pure condition, but the authors had succeeded in preparing the butylic compound in a satisfactory manner. This aluminic butylate is a solid body at the ordinary temperature, but melts when heated, and is capable of distillation. It is very soluble in anhydrous ether or benzole, from which it separates on evaporation without crystallising. It is decomposed by water, butylic alcohol and alumina being produced. Its composition was found to be $Al_2(C_4H_9O)_6$. There is also evidence of an intermediate compound, soluble in water, which is probably homologous with the aluminic iodo-ethylate $Al_2I_3(C_2H_5O)_3$.

On the Amounts of Sugar contained in the Nectar of Various Flowers, by Alex. S. Wilson, M.A., B.Sc.—Nectar, the sweet-tasting fluid found within the cups of insect-fertilised flowers is of use to the plant by affording an inducement whereby insects are attracted to visit the flowers. By this means cross-fertilisation is effected, as bees, butterflies, and other insects bring with them pollen from other flowers adhering to their bodies which they deposit on the stigmas. Mr. Darwin has shown experimentally what an additional amount of vigour is thus conferred on the resulting seeds in contrast with the degenerating effect of continuous inbreeding. Very often this sweet fluid is exuded from special glands, but in other cases from portions of the flower that do not seem to have been specially adapted for this purpose. Morphologically nectaries may represent very different structures, but not unfrequently they are of the nature of an aborted organ such as a petal or stamen. It is a disputed point among biologists whether this saccharine matter is a true secretion or simply an excretion of effete matter from vegetable cells—a bi-product of the chemical changes taking place within these cells. Nectar is of course the source whence the bee derives honey, but it also affords sustenance to many different kinds of insects as well as humming-birds. The bright colours of flowers as shown by Sir John Lubbock's experiments serve for the guidance of insects to them, and the odours which they emit fulfil the same end. The markings on a flower's petals, too, always converge towards the nectar. The importance of these guides to insects will be apparent from the following estimations which show how indispensable it is that as little time as possible should be lost by an insect while collecting honey. It must be remembered also that in order to protect the nectar from rain it is usually contained in the least accessible part of the flower. The formation of nectar is observed to take place most freely in hot weather, so great, however, is the economy of the plant that it is only formed at the time when insects' visits would be beneficial, *i.e.*, when the anthers are shedding their pollen or when the stigma is mature. Biologists believe that the visits of bees, butterflies, and other insects have in past time exercised an important influence in modifying the size, shape, colour, &c., of flowers. The following determinations are of interest as showing to what extent this action goes on and as a help towards ascertaining the value of this factor:—

Sugar in Flowers.

		Total.	Fruit.	Cane.
1. Fuchsia, per flower	mmg.	7·59	1·69	5·9
2. Everlasting Pea, per flower...	,,	9·93	8·33	1·60
3. Vetch, per raceme	,,	3·16	3·15	·01
4. ,, single flower ...	,,	·158	·158	—
5. Red Clover, per head... ...	,,	7·93	5·95	1·98
6. ,, ,, floret... ...	,,	·132	·099	·033
7. Monkshood, per flower ...	,,	6·41	4·63	1·78
8. *Claytonia almoides*, per flower	,,	·413	·175	·238

Approximately, then, 100 heads of clover yield ·8 grm. sugar or 125 give 1 grm. or 125,000 1 kilo sugar, and as each head contains about sixty florets it follows that 7,500,000 distinct flower tubes must be sucked in order to obtain 1 kilogrm. sugar. Now as honey roughly contains 75 per cent. of sugar, 1 kilo. is equivalent to 5,600,000 flowers in round numbers, or say two-and-a-half millions of visits for 1 lb. of honey. Another point worthy of note in these results is the occurrence of what appears to be cane-sugar, and that in the case of fuchsia in the proportion of three-fourths of the whole. This is remarkable, as honey is usually supposed to contain no cane-sugar, its presence being generally held as certain evidence of adulteration. The question therefore arises whether this change, which occurs while the sugar is in the bees' possession, be due to the action of juices with which it comes in contact while in the honey-bag, or whether on account of the acid reaction of nectar it may not take place spontaneously.

Notes on Waters from the Severn Tunnel Springs, by W. Lant Carpenter.—The plans for the construction of this tunnel had

been described by Mr. Charles Richardson, its engineer, to Section G, at the Bristol meeting in 1875. In June, 1878, the trial heading had been driven more than half-way under the Severn, and the most difficult part had been overcome. In the opinion of the engineer, the water in the tunnel springs—one of which had yielded 300 gallons per minute—was not Severn water, but derived from springs in the pennant and other strata, and the salt from the occasional beds of salt in the Bristol coal-field. The author had analysed water from four springs, and compared the results with those from Severn water at various times of the tide, and with water from wells on the English side sunk forty feet through the alluvium. The results were arranged under the heads of specific gravity, total solid residue, and total chlorine per cent. The author found it difficult to avoid the conclusion that the water in the springs was chiefly Severn water.

SECTION C.—Geology.

The Geological Relations of the Atmosphere, by T. Sterry Hunt, LL.D., F.R.S.—The author began by noticing the inquiries of Ebelmen into the decomposition of rocks through the influence of the atmosphere, resulting in the fixation of carbonic acid and oxygen, and discussed the question at length, with arithmetical data. He inquired farther into the fixing of carbon from the air by vegetation, with liberation at the same time of oxygen both from carbonic acid and from the decomposed water, the hydrogen of which, with carbon, forms the bituminous coals and petroleums. It was shown that the carbonic acid absorbed in the process of rock-decay during the long geologic ages, and now represented in the form of carbonates in the earth's crust, must have equalled, probably, two hundred times the entire volume of the present atmosphere of our earth. This amount could not of course exist at any one time in the air; it would, at ordinary temperatures, be liquefied at the earth's surface. Whence came this vast quantity of carbonic acid, which must have been supplied through the ages? The hypothesis of Elie de Beaumont, who supposed a reservoir of carbonic acid stored up in the liquid interior of the planet, was discussed and dismissed. The gas now evolved from the earth's crust from volcanic and other vents was probably of secondary origin, and due to carbonates previously formed at the surface.

The solution of the problem offered by the author is based upon the conception that our atmosphere is not terrestrial, but cosmical, being a universal medium diffused throughout all space, but condensed around the various centres of attraction in amounts proportioned to their mass and temperature, the waters of the ocean themselves belonging to this universal atmosphere. Such being the case, any change in the atmospheric envelope of any globe, whether by the absorption or the disengagement of any gas or vapour, would, by the laws of diffusion and static equilibrium, be felt everywhere throughout the universe, and the fixation of carbonic acid at the surface of our planet would not only bring in a supply of this gas from the worlds beyond, but by reducing the total amount of it in the universal atmosphere, diminish the barometric pressure at the surface of our own and of all other worlds.

This conception of a cosmical atmosphere, of which our own forms a part, is not new, but was put forth by Sir William R. Grove in 1843, and is developed in the very learned and ingenious work of Mr. Mattieu Williams, on "The Fuel of the Sun," and has lately been noticed by Dr. P. M. Duncan in its geological bearings. Ebelmen, in 1845, pointed out that the greater weight of an atmosphere charged with carbonic acid would increase the temperature due to solar radiation at the earth's surface, and greatly modify atmospheric phenomena.

Tyndall, by his subsequent researches on radiation, showed that certain gases, in amount too small to affect considerably the barometric pressure, might influence powerfully climatic conditions, and suggested that in the former presence in the atmosphere of moderate quantities of a gas like carbonic acid, might be found a solution of the problem of the climates of former geologic ages. According to the author, the amount of this gas, which, since the advent of life on our earth, has been subtracted from the universal atmosphere, although it may not have sufficed to diminish by more than a small fraction the pressure at the earth's surface, would account for all the conditions of geological history so far as temperature and climate are concerned.

He maintains that while we have evidence of a warm or subtropical climate prevailing over the Arctic regions from the carboniferous down to lower cretaceous times, and a gradual refrigeration up to the temperate climate of the miocene age, we had for the first time in the pliocene age the evidence of Arctic cold, which, with some variations, has continued until now. Since that date geographical variations have caused, and may again cause local climatic changes of considerable magnitude. But no such changes could permit the existence over continental areas within the Arctic circle, of such tropical vegetation as we know to have once flourished there. Geographical changes, as J. F. Campbell, Dawson and others have so well pointed out, might lift large areas into the region of perpetual frost, and thus give rise to local glacial phenomena, and may, moreover, account for considerable local climatic variations at the sea-level since the pliocene age. We cannot, however, account in this way for the warmer climates of previous ages, but must seek for their cause in the former constitution of the atmosphere.

Touching the suggestion that former climatic changes were due to a displacement of the earth's axis of rotation, the author expressed the opinion that it is irreconcilable with the fact long ago insisted upon by him that "the direction of the Arctic currents, which are guided by the earth's rotation, appears, from the distribution of marine sediments, to have been the same since very early periods." Dawson has reinforced this argument by recalling the fact that the southward migration of successive floras shows, in like manner, that from the Devonian age the general courses of oceanic currents, and consequently the position of the earth's axis, have not changed.

On the Filtration of Sea-water through Triassic Sandstone, by Isaac Roberts, F.G.S.—Mr. Roberts stated that he was led to investigate the effects produced on sea-water by filtration, in consequence of the constantly-increasing salinity of the water drawn from several wells in Liverpool which are sunk below the sea-level in the Bunter sandstones of that locality. He found that one of the wells, which he selected as the type of the rest, yielded water which increased in salinity at the rate of 4·91 to 5·81 per cent. annually, and inferred that the sandstone rock had the power of removing salts out of sea-water. To prove this he filtered sea-water through blocks of the sandstone, and found the inference to be greatly borne out by the results of his experiments. Two cubic feet of the stone removed from the first filtrate of 3½ fluid ounces of the water 80·8 per cent. of the salts held in solution, and each measured quantity of four ounces, which were afterwards filtered through, regularly showed an increase of the salts in solution, until 93½ fluid ounces had filtered through the stones. Then these ceased to be operative as filters, and the waters passed through unchanged. After allowing the stones to dry he passed spring water through them, and found that the salts which they had taken up were again removed and washed out, thereby showing the action to be mechanical.

New Geological Map of India.—Mr. W. Ball, M.A., presented and explained a new geological map of India which will shortly be published, with a manual. He mentioned that there were 8,000 square miles of coal measures in India. It was of an inferior character, and was unfortunately in the most inaccessible part of the country.

Mr. W. H. Baily, M.R.I.A., F.G.S., read a paper *On some Additional Labyrinthodont Amphibia and Fish from the Coals of Jarrow Colliery, near Castlecomer, County Kilkenny*.—These fossil remains, which were found below a bed of coal three feet in thickness, were all impressed on the true coal, and had, in fact, turned into carbon. One of them, which was almost perfect—*Megalichthys hibberti*—was three feet seven inches in length. This one locality had yielded a larger number of these fossils than all the other coal-fields in Europe.

On the Ancient Volcanic District of Slieve Gullion, by Joseph Nolan, M.R.I.A., Geological Survey of Ireland.—Slieve Gullion is a mountain situated some few miles north of Dundalk, west of the hilly country lying between the bays of Dundalk and Carlingford. The rocks which mainly compose it are of a plutonic character, consisting of dolerites and elvanites, and have been erupted through granite of lower Silurian age, probably about the close of the palæozoic epoch. On the west and south of the mountain the elvanite forms a dyke-like ridge when it changes from a granitoid rock to a felstone porphyry. Simultaneously with this change, suggesting conditions of less intense heat and pressure a remarkable fragmentary rock makes its appearance. It is here almost altogether composed

of granite fragments, farther south a mixture of granite and slate, and at the south-east almost exclusively of slate *débris*. At all these places it is so intimately associated with the porphyry that any demarcation between them is impossible, and there can be no doubt that it is due to the broken and disintegrated crust, shattered by the force of the volcanic explosions. That the eruption differed from volcanic explosions of the normal character is evident from the absence of fragments of lava or scoriæ. It was in fact entirely aëriform, the volcanic activity having evidently been subdued by the sudden dissipation of the elastic gases in that part of the dyke which alone reached the surface, aided by the immense weight of displaced materials falling back into the gulf.

The president remarked that the paper opened up several points of interest, especially in illustrating the passage of granitic into volcanic rocks; and in bearing out the views of Prof. Judd on these points, giving undoubted proof of the change from granitoid rock into one by which its protrusion has produced mechanical accompaniments.

On Some Fossils from the Northampton Sands, by John Evans, D.C.L., LL.D., F.R.S.—These fossils from the ironstone beds of Durton, near Northampton, are casts of lithodomous borings originally made in lumps of coral, impressions of which they still bear on their outer surface. In the interior the presence of the shells is still to be traced. Their history appears to be that the cavities were first filled with limonite, subsequently converted into carbonate of iron, and eventually hematite. Last of all the inclosing coral has been entirely removed by the infiltrations of water charged with carbonic acid. This last process has probably taken place since the emergence of the beds from below the sea-level. The Northampton Sands have been fully described by Mr. Samuel Sharp, F.G.S., in the *Quarterly Journal* of the Geological Society.

A paper was read by Mr. H. W. Baily, F.G.S., *on a New Star-fish from Lower Silurian Caradoc Strata, Co. Wexford, and some New Carboniferous Limestone Mollusca from the County of Limerick.*—The starfish, of which a number of very perfect specimens had been collected through the exertions of Mr. H. Kinahan, during the progress of the Geological Survey, was named by Mr. Baily *Palasterina kinahana*. The carboniferous limestone fossils were all molluscan shells, principally cephalopods, belonging to *Nautilus goniatites* and *Orthoceratites*, with a few bivalves and univalves belonging to *Cardiomorpha macrocheilus*, &c.

On the Saurians of the Dakota Cretaceous Rocks of Colorado, by Prof. E. D. Cope.—This paper was illustrated by crayon-drawings of the bones, of the natural size, which well illustrated the gigantic proportions of the several species. The first described was the *Camarasaurus supremus*, Cope, of one individual of which a large number of bones have been found. The vertebræ are opisthocœlous, and their centres are hollow, with the internal cavity divided into two chambers by a septum. The caudal vertebræ and limbs are solid, or nearly so, and the neck is long. The scapula is enormous, measuring 5½ feet in elevation, so that the fore limb was probably as long as or longer than the hind limb. There are four sacral vertebræ and the femur is six feet in length. The elevation to the top of the head was probably 26–28 feet. The description of three species of *Amphicœlias* followed. The type *A. altus*, Cope, presents the same kind of chambers of the vertebral cerebrum as *Camarasaurus*, but the articular extremities are both concave. Both genera possess a new articular element, called by Prof. Cope a hyposphen. This is the reverse of the zygosphen, standing below the postzygapophysis, and looking upwards and outwards. The neural spine of *Amphicœlias* is anteroposteriorly placed, that of *Camarasaurus* transversely, and in the latter, in the dorsal region, it is divided to the base, and the halves separated. *A. altus* was as large as *C. supremus*, the femur measuring six feet and the dorsal vertebra 3·5 feet elevation.

Prof. Cope then indulged in some reflections as to the habits of the genera so remarkable for their thin-walled dorsal and cervical vertebræ. He was of the opinion that the caverns were not filled with cartilage but with diverticula from the lungs or other air-cavities. Prof. Cope advanced the hypothesis that the species of *Camarasaurus* and *Amphicœlias* were dwellers in water of sometimes considerable depth, where they walked on the bottom, and browsed on the algæ and sometimes aërial vegetation growing on the coast. The long fore-limbs and long neck of *Camarasaurus* were further evidence that the animal reached upwards for food, as the giraffe, or for air when submerged.

Prof. Cope concluded by remarking that the Dakota epoch had been referred to the middle of the European cretaceous series on the evidence of the mollusca and plants, but now the vertebrata parallelise it with some portion of the Jurassic series in the wide sense.

Prof. Hull, F.R.S., gave a sketch of the geology of the environs of Dublin.

On the Progress of the Geological Survey of Ireland, by Prof. Hull, M.A., F.R.S., Director (communicated with the sanction of the Director-General).—The author gave a short account of the origin and progress of the Geological Survey from its commencement in 1832, under the late Gen. Portlock, R.E., down to the present day, stating that the whole country south of a line drawn roughly from Larne on the coast of Antrim to Sligo had been surveyed, while 160 sheets of the geological map, on a scale of one inch to the statute mile, had been published.

Along with the maps there had been issued seventy-eight separate explanatory memoirs, describing the structure and palæontology of 126 sheets. It had also been found necessary to revise the geology of the Leicester and Tipperary coal-fields, the carboniferous trap-rocks of county Limerick, and the south-east portion of the country, including parts of Wicklow and Wexford. The coal-fields of the north of Ireland had also been surveyed, and published in the maps both of the "6-inch" and "1-inch" scales; and it was also intended that the districts of county Antrim containing the pisolitic iron ores should be illustrated by maps on both these scales. The district still remaining to be examined includes the greater portion of Donegal, Tyrone, Sligo, Fermanagh, and Antrim.

On the conclusion of Prof. Hull's paper *On the Progress of the Geological Survey*, the President said they must all congratulate the chief of the Geological Survey in Ireland on the progress that had been made, but he hoped that however long he might live in the occupation of that high post, the survey would never be absolutely completed. It was quite right to re-examine surveys that had been made; for, from time to time discoveries were made which threw a further light on the geological views of the district, and which must be taken into account before an absolutely complete survey could exist. Therefore, though the survey had progressed so much, still he hoped it would be long before it was completed. He wished to say one word which appeared to him of importance, not only to the Geological Survey of Ireland, but of England also. The object of these surveys was to make the public at large thoroughly acquainted with the geology of the country in which they resided. Maps were carefully drawn and memoirs published from time to time in illustration of the maps; but, unfortunately, so far as the diffusion of knowledge was concerned at the present time, not owing to any prohibition of the Geological Survey, but owing to some mistaken view on the part of the Treasury, prohibitive prices were placed upon the geological memoirs. He had seen small pamphlets priced at 16*s*. or 17*s*., though these pamphlets were printed and published at the public expense for the benefit of the public. He held in his hand a very small pamphlet, which was published at 9*s*. He did not think a false economy of this kind ought to be suffered to go on without a protest on behalf of those who were interested in geological progress. He therefore felt it right to make these remarks, in the hope that possibly this Association or some other learned bodies might take steps to bring this matter under the consideration of the Treasury, and point out how with the one hand they were lavishly spending money for the advancement of geological knowledge, and with the other withholding it from the public.

Dr. Sterry Hunt said that in the State of Pennsylvania the reports and memoirs were printed and stereotyped, and then offered to the public for the mere cost of printing and paper. The memoir on the table priced at 9*s*. would be sold there for 2*s*.

Mr. Tiddeman said, with respect to the prices of the geological publications, he should be sorry any one should think that the Survey was responsible. It could not be more disagreeable to any than to the Survey themselves to find that their labour was almost entirely thrown away by reason of the high prices of the publications when they came out in the miserable manner in which they were produced, and which would almost disgrace a fifth-rate publishing firm.

On the Influence that Microscopic Vegetable Organisms had in the Production of some Hydrated Iron Ores, by M. Alphonse Gages, M.R.I.A.—In the tanks of the Royal College of Science, Dublin, there are considerable deposits of hydrated peroxides of

iron formed by the agency of Penecilliæ, which accumulate in large sponge-like masses so as to intercept the flow of the water. The author points out the connection between such deposits and iron-ore formations.

Notes on some New Fossils "Eribollia Mackayi," from the Quartzites of Loch Eribol and other Parts of the Western Highlands of Scotland, by James Nicol, F.R.S.E. (with photograph of the rock).—The fossils were discovered by Mr. Donald Mackay, early this year, in the Assynt quartzites of Lough Eribol, lying below the Durness limestones, in which fossils have been more abundantly found. The surface of the rock shows the ends of more than a dozen bodies, more or less rounded in form, running down into the interior of the stone, and tapering to a point. They show a central core with an outer wall around it. There is no doubt they are organic. The author rather inclines to regard them as corals approximating at least in form to *Cyathophyllidæ*. Thin slices might perhaps decide this question, but meanwhile the author has named them *Eribollia Mackayi*, indicating the locality and the finder. These and other fossils give the author no reason to reverse the relations of the strata in the north-west Highlands held by him, but much to confirm them.

Concerning the Extent of Geological Time, by Rev. M. A. Close, F.G.S.—Since geology has her own strong and unrefuted arguments for the great extent of geological time, it is not logically necessary for her to do more than show, if it can be shown, that the physical arguments for the very inconvenient restrictions thereof rest upon still unproved assumptions. The argument from the rate of cooling of the earth seems to have been satisfactorily shown by Mr. T. Mellard Reade to be quite inconclusive. The argument from the probable duration of the sun's radiation of heat assumes, *inter alia*, that the original nebula from which the solar system was formed was cold, and also that the unit of gravitation relatively to the mass of that system has been constant from the time when that mass began to fall together, and throughout the enormous interstellar distance which has doubtless been traversed by it since that time. Dr. Croll's suggestion in answer to the former of these assumptions is logically sufficient as a reply to the whole of this argument. Nevertheless it may be added, as to the latter assumption, that those physicists who have entered upon certain speculations as to the cause of gravitation, cannot deny that it is perfectly credible, and even probable, that gravitation is not an essential accompaniment of matter, and that the unit of gravitation may not be constant throughout all time and space. The arguments from the earth's figure in connection with the retardation of her rotation by the ocean tide depends on the doctrine of the steel-rigidity of the earth taken all together, as do also the calculations of various writers on subjects which bear in different ways on the present one. However, Sir W. Thomson himself has greatly weakened the support of this doctrine. But geology (as regards the matter in hand) is not concerned to question it, although it is, at first sight, a difficulty. The results obtained by the Tide Committee of the Association point to the conclusion that there is an 18·6 year-tide in the body of the earth depending on the revolution of the moon's nodes, and that the rigidity of the earth, even if it be in one sense as high as that of steel, is yet a *viscous* rigidity, by which she may yield almost indefinitely to sufficiently long-continued straining forces. Other considerations confirm this latter position. This 18·6 year-tide, whether resulting from such *viscosity* proper or from plasticity of a different kind, must cause a variation in the earth's rate of rotation during the same period. This variation would probably be desirable if looked for by the astronomers, who would confer a boon on the geologists by endeavouring to detect it. Dr. John Evans' suggestion of the possible considerable mobility of the axis of rotation relatively to the body of the earth, bears in certain ways on the present question; the mechanical objection to it, already greatly weakened by the Rev. O. Fisher, might be quite removed by the investigation suggested.

On some New Pre-Cambrian Areas in Wales, by Henry Hicks, M.D., F.G.S.—During some recent researches in Wales the author has been able to add many new areas to the pre-Cambrian rocks already described. In these examinations he has been assisted at different times by Prof. Torrel, of Stockholm, Prof. McKenny Hughes, Mr. Tawney, F.G.S., and Dr. Sterry Hunt, of Montreal. The additional areas to be now added to those previously known are:—

1. Some cupriferous schists with their associated greenstone bands (the so-called intrusive greenstone of the Geological Survey) to the north of Dolgelly, and including a great portion of Robel Tawr.

2. Masses of granitoid rocks, porphyries, and greenstone breccias, in the neighbourhood of Pwllheli.

3. The porphyries and granitoid rocks forming Myaydd Mynytho, and extending in a northerly direction towards Nevin, including also Nevin mountain and the porphyries and greenstone breccias to the north-east of Boducan.

4. The Bhos Hirwain syenite and the so-called altered Cambrian beds to the west of that mass in Caernarvonshire, and also Bardsey Island.

5. The granitoid rocks, felstones, and porphyries, forming the Rivals (yr Eifl) range of mountains.

6. The so-called altered Cambrian rocks to the west of the Penygroes porphyry.

7. The so-called intrusive granite in Anglesea, and the whole of the area marked as altered Cambrian in that island. In addition to these he has also extended some of the areas and defined more clearly the order of superposition of these rocks in Pembrokeshire. In North Wales, as in South Wales, he found that the pre-Cambrian rocks resolved themselves into three well-marked and very distinct types, and that these indicated separate formations, each of which, on careful examination, and when found in juxtaposition, proved to be unconformable to the other. At St. David's the granitoid rocks occur at the base, and, resting unconformably upon these, are found the quartz-felsites. These are again succeeded unconformably by the agglomerates, breccias, greenstone bands, and schists of the Pebidian group.

In North Wales this was also exactly the order in which the various rocks were found to succeed each other, but the middle or quartz-felsite group was found more largely developed in Caernarvonshire.

As this middle group had not previously been separated under a distinguishing name, the author now proposed to adopt for it the name *Arvonian*, from the Roman name *Arvonia*, and from which the present name of Carnarvon is derived. So many of the large ridges and lofty mountains of Carnarvonshire are composed of these felsitic rocks that it appeared to the author and his friends that this name would be very appropriate for the formation. The distinguishing characters most marked in these three pre-Cambrian formations may be briefly summed up as follows:—

1. *Dimetian:* Granitoid gneiss rocks.
2. *Arvonian:* Quartz, felsites, and porphyries (Halleflinta of Torrel; petro-silex rocks, Hunt).
3. *Pebidian:* Green and purple agglomerates and breccias, green chloritic schists, with massive greenstone bands, talcose schists, &c.

In these formations the bedding is usually easily recognised, but at present the actual stratigraphical thickness cannot be correctly estimated. It is perfectly clear, however, from the sections exposed, that each must have a vertical thickness of many thousand feet. That they have a very extended geological distribution over the British islands is also daily becoming more and more evident.

On the Metamorphic and Intrusive Rocks of Tyrone, by Joseph Nolan, M.R.I.A., &c., of the Geological Survey of Ireland.—The rocks described in this paper occupy the central parts of county Tyrone extending from Omagh eastwards and north-eastwards towards Slieve Gullion. They consist for the most part of an amorphous green hornblendic rock, in the midst of which is a wide lenticular tract of micaceous gneiss and schist. The author shows that these two classes pass gradually into each other, and that even among the amorphous hornblendic rocks traces of schistose structure can generally be observed, while local transitions into schists frequently occur. Gradations into more crystalline rocks were also noted and described, those of a hornblendic character passing into a felspathic variety in which little or no hornblende occurs, while quartz and orthoclase are developed, so that a coarse quartz porphyry is produced, passing ultimately into granite.

It was also shown that some of the granite was intrusive during the period of the old red sandstone, a new fact in Irish geology. Its association with metamorphic rocks, probably of lower Silurian age, was explained on the hypothesis that the intrusive granite was due to re-metamorphism of the later period, so that portions of the already crystalline rocks were completely fused and became irruptive. That metamorphic action in this district continued up to and even after the old red

sandstone age seems to have been the opinion of the late Gen. Portlock, who in his geological report on Londonderry, with parts of Tyrone, &c., has described these rocks and their relations to each other at considerable length. He does not seem to have considered the granite to be intrusive, but merely a metamorphosed condition of what we now call the lower carboniferous sandstone, which was then classed with those of the old red formation.

On the Cervus Megaceros, by W. Williams.

On the Occurrence of Certain Fish Remains in the Coal Measures, and the Evidence of the Fresh-water Origin of the Coal Measures, by James W. Davis, F.G.S.—These occur in a bed of cannel coal, and more particularly in the impure cannel above and below it, in the district of Morley and Adwalton, near Leeds. They consist of both Elasmobranchs and Ganoids, but by far the most common are *Cœlacanthus lepturus*. The fresh-water nature of the cannel coal and the internal anatomy of the Cœlacanthus, together with occurrence of Labyrinthodonts, lead to the conclusion that the strata were of subaqueous, and probably fresh-water origin.

On the Age of the Crystalline Rocks of Donegal, by Prof. W. King, D.Sc.—The author had succeeded in obtaining some true fossils in portions of the Innishowen limestone that have scarcely undergone any change. He had not had time to examine them as closely as he would have wished, but they appeared to be identical with Caradoc Bryozoon from the Desertcreat schists of Tyrone, which Portlock has called *Ptilodictya dicotoma*. This was the first example, as far as he could ascertain, of an undoubted fossil having been detected in these limestones. The fact may be taken as evidence that these deposits and their associated argillaceous and siliceous masses are of the lower Silurian age, and it seemed highly probable that the more intensely metamorphosed rocks in the north-west division of Donegal belonged to the same geological period.

On the Cervus Megaceros, by W. Williams.—The author considered that in some excavations he had made at Ballyhetagh Bog, near Dublin, he had met with evidence which led him to differ from former views as to the time of these animals' existence. He asserted that the clay on which the remains rested is the *lower boulder clay*. He considered the animal lived during the middle glacial period, and was killed off by the cold of the *uppper boulder clay* period.

Prof. Leith Adams, F.R.S., questioned the accuracy of Mr. Williams' views. There was no evidence for such a division of glacial beds in the locality in question, as Mr. Williams had mentioned, nor was there any proof that the animals had been destroyed by the intervention of a cold period. In England there is authentic evidence of the co-existence of this animal with man.

After the discussion on the *Cervus megaceros*, the president submitted the following lines:—

"Small comfort to the stag that's mired,
To think that in long distant ages
He'll be dug out to be admired,
And have his life discussed by sages."

which Mr. Pengelly capped as follows:—

"Yet had he known their fearful puzzle,
How far from truth each sage would be,
Methinks he'd rear his cervine muzzle,
And scent the future Section C."

SECTION D.—BIOLOGY.

Department of Anthropology.

Miss A. W. Buckland read a paper *On the Prehistoric Monuments of Cornwall compared with those in Ireland.*—In the course of her paper Miss Buckland said that the prehistoric monuments of Cornwall, believed by archæologists to be the work of the same race as those of Ireland, presented, in the midst of strong resemblance, certain points of difference which deserved the attention not only of archæologists but of ethnologists. In both countries they consisted of tumuli, including chambered barrows and giants' graves, monoliths or menhirs, circles, cromlechs or dolmens, and holed stones, all probably sepulchral and hut circles, cliff castles, curious caves and crosses, whilst in Ireland they found in addition earthworks called raths, and round towers. Long barrows, which were looked upon as the most ancient of burial places belonging to the stone age, were wanting in both countries, hence we may infer that the people who then existed in England and Scotland never inhabited Cornwall and Ireland, where the earliest barrows seem to belong to the bronze age, the mode of interment in Cornwall being chiefly by cremation; but these tumuli may not represent the earliest tombs in these countries.

Mr. W. J. Knowles read a paper *On Flint Factories at Portstewart and Elsewhere in the North of Ireland.*—The paper contained a further account of a find of flint implements found in sandhills at Portstewart, county Londonderry, near the mouth of the River Bann, which consisted of a large quantity of scrapers, some arrow-heads, bone implements, hammerstones, and flakes, with shells, broken bones, and pottery. These were found in hollows amongst the sand, but were supposed to have dropped from black layers on the sides of the pits as the sand was removed by the wind. The black layer represents the ancient surface, and similar objects have been dug out of it. The only new find since the subject was last brought before the British Association was some porous lava and flakes of obsidian. These substances are not found native, as far as the author could learn, and he believed they must have floated a distance, probably from the West Indies. He also described other places which he had explored in the neighbourhood of Castlerock, county Londonderry, and Ballintoy, county Antrim, where similar remains were found, and the same kind of black layers are to be seen. The black layers, when not destroyed or uncovered by denudation, are covered up with sand from ten to twenty feet in thickness, which is protected on the top, but is gradually wearing away where exposed at the sides. The animal remains were submitted to Prof. A. Leith Adams, of the Royal College of Science, and he decided that they contained man, horse, ox, hog, dog or wolf, fox, and deer. He also described objects from Larne, some of which were found nine feet from the surface, and he exhibited a photograph of a mammoth's tooth, found in a small delta-like field near Larne, which is now in the possession of the Rev. Dr. Grainger, M.R.I.A., of Broughshane, county Antrim, and flakes and rude implements from the same field. He also showed and described a series of rude implements thick at the one end, for holding in the hand, and pointed at the other, of the palæolithic form. Although there were no animal remains found with them they were taken from the diatomaceous deposit below the peat, where remains of the Irish elk are usually found, and the author drew attention to a statement of Dr. John Evans in his "Stone Implements of Great Britain," where, on comparing the implements found in the caves and those in the old river drifts, he says—"the large-pointed implements are mostly found in the latter;" and gives as his reason for their being found mainly there that they were probably used "for out-of-door purposes." The author states that it was strange that his large implements of similar form were found mainly in the bed of a river, and suggested that the rivers and that form of implement had probably some connection, and that they were not used for "out-of-door purposes" only. Reference was next made to the age of the implements found in Ireland, about which he said authors were not agreed, and the author again quoted from Evans' "Stone Implements," and showed that the descriptions of many of the palæolithic implements in that work would apply to the Irish ones, and concluded that we must either carry man farther back than the so-called neolithic age, or give up some of our theories regarding the distinguishing characteristics of the palæolithic and neolithic implements.

Mr. V. Ball, M.A., exhibited a number of objects of ethnological interest, collected in the districts of India, and also in the Nicobar and Andaman Islands. These included stone implements, battle-axes, an instrument like a boomerang used in killing small animals, but which was not capable of the return motion of the Australian boomerang, arrows, musical instruments, &c. There was a curious wooden figure, not an idol, but an effigy of some departed person, with a sort of girdle round the waist, which hung down like a tail behind; and the author thought it explained the ancient tradition of men with tails in those islands. Another singular item consisted of two ornamental skulls, in reference to which Mr. Ball mentioned that on the death of an Andamanese his body was placed on a tree, and as soon as his bones became bleached his skull was taken and ornamented, and first carried about by his widow, and afterwards by other members of his family. The collection included some photographs, one of which represented buildings on piles in water.

Mr. T. J. Hutchinson, lately her Majesty's Consul at Callao, read a paper entitled *Habits and Customs amongst some Tribes of*

Tropical Aborigines.—The tribes spoken of were some of those in West Africa and South America, with whom he had been acquainted during twenty-three years. The object of the paper was to show analogies in superstition and social barbarities, as well as in a sort of indigenous civilisation amongst people of different races dwelling on different sides of the globe, and with respect to whom there was no evidence of their having ever been in communication with each other.

M. Henri Martin, the French historian, read a paper written in French, entitled *Les Races anciennes de l'Irlande ; Utilité de l'Étude des Traditions qui les concernent pour l'Ethnographie de l'Europe primitive.*

The chairman, Lord Talbot de Malahide, said they must all be very much flattered at the interest which M. Henri Martin had taken in the ancient history and traditions of Ireland. He had shown in how many respects those traditions were connected with the traditions of the Continent, and how much light they threw on the migrations of the principal races which had colonised Europe.

Mr. H. H. Howorth made a communication on the *Spread of the Slavs.*—He said that if they excluded the Turks from Roumelia and Bulgaria, the Basques from Spain, and the various tribes of Finns from the north-east of Russia, they should have a tolerably homogeneous population left in Europe, which might be divided into the Celts, in the West; the Teuton in the centre, and the Slavs in the East. The ethnology of the Slavs had only been recently treated on a scientific basis. They owed this to the researches of Count Polocki and Shafarick, the results of which, together with some of his own, he would bring before them. Patriotic Russians derived the name *Slav* from *Slova*—glory—a derivation improbable, when it was remembered that the name was very recent, not occurring before the sixth century. Shafarick believed that *Serb* was the oldest name of the Slavs, but that also was a modern name, and appeared to be of foreign origin. The oldest name of the Slavs was that by which they were known to the Germans—namely, *Wends*, a name occurring in classical writers under the form of Veneti. It was curious that the name *Slav* (slave) and *Servus* (Servian) should both indicate a people of servile condition. The Emperor Constantine, who gave the first account of the Servians, said that the name Servian was derived from the fact that they served the Roman emperor. About the Christian era, there was a great revival amongst the races of Eastern Europe. The power of various nomades of South Russia, who are now known to be of Aryan origin, was broken by the Romans. That enabled the Turkish and other nomades east of the Volga to invade Europe; and they drove the Aryans to the centre of Europe, where they settled in the country about the Carpathians. This accounted for the fact that amongst the Poles and Bohemians the upper classes were entirely distinct from the lower, the Polish grandees being derived from the immigrants, while the peasants belonged to the old stock of Slavs. Afterwards the Turks and Huns pushed into Europe, driving the Slavs still further, and causing in the sixth century a great migration of them south of the Danube, where they overran Bulgaria, European Turkey, and the mainland of Greece. Others were driven to the Dalmatian coast and islands. The Emperor Heraclius, in order to protect himself, invited the Slavs of the Carpathians, called Croats, and the Serbs, to his assistance. The name Croat was derived from their living in the mountain districts. *Chrebet* and *Carparthian* being the same word. One section of the Serbs who lived on the river *Bosna* were called Bosnians; another, who inhabited the Black Mountains, were called Montenegrins. A third section inhabited a district which was afterwards created into a dukedom by the Emperor of Austria, on whom they were dependent, and were called Herzegovinians from the German, *Herzog*, a duke. The rest of the Serbs formed the Servian community. All these were of one race, and had the same traditions, the only difference being that the Croats were converted to Roman Catholicism, while the Serbs became the converts of Greek priests; and hence arose their existing religious differences. The Slavs of Eastern Thrace were conquered in the seventh century by a race of intruders closely allied to the Magyars of Hungary, and known as Bulgars. Their descendants were the dominant class in Bulgaria, and had the high cheek bones and oblique eyes of their race. The speaker concluded by describing the various migrations of the Russian Slavs.

Prof. Daniel Wilson, F.R.S.E., of Toronto University, read a paper *On some American Illustrations of the Evolution of New Varieties of Man.*—He said abundant traces were apparent of the intrusion into Europe in prehistoric times of one or more races superior alike in physical type and in the arts upon which progress depends to the primitive races. Furthermore it was assumed that an admixture took place between a fair, tall, intrusive race and the primitive Australioid savage of Western Europe, resulting in the so-called Melanochroi, still abundant in Britain, France, and elsewhere. On turning to the American Continent, they saw vast regions occupied exclusively, until a comparatively recent date, by tribes of savage hunters, upon whom the highly civilized races of Spain, France, and England have intruded with results in many respects so strikingly accordant with the supposed evolution of the Melanochroi of modern Europe, that they seemed to look upon an illustrative series of ethnological experiments carried on, on the amplest scale, and begetting synthesis altogether confirmatory of previous inductions. The intermingling of very diverse races at present taking place on the American Continent, was indeed complex and varied. Hybridity was the result on a great scale, and the process had already been perpetuated sufficiently long to beget important indications of the possible evolution of permanant hybrid varieties. A new race, as among the tribes of half-breeds of Manitoba, was seen as it were in the very process of evolution; while, sheltered within the remote Arctic North, man could be studied among the Esquimaux in conditions closely analogous to those which are ascribed to post-pliocene if not to pre-glacial man. In the abrupt collision of the civilized races of Europe with the American aborigines, it had been taken for granted that the latter were doomed to inevitable extinction, and were to be replaced by the purely intrusive race of the Old World. A growing feeling was manifested now, alike in the United States and in Canada, in favour of the idea that the Indian population was not wholly disappearing by extinction, that a much larger amount of healthful intermixture and consequent absorption had taken place than unobservant critics had any conception of, and that the native Indian element was a factor in the population of the New World, destined to exercise an enduring influence on the ethnical character of the Euromerican race. If so, and the result was to be the perpetuation of permanent traces of the native American man in the mixed race of settlers by whom the vast forests and prairies of the New World were being converted to the uses of civilized communities, rivalling Europe in all the highest elements of progress, it would be no more than had been already recognised in the mixed races of Europe.

Mr. A. L. Lewis read a paper *On the Evils arising from the Use of Historical National Names and Scientific Terms.*—The propositions endeavoured to be established by Mr. Lewis were: (1) That there were at the first population of Europe certain primitive races, of which three are particularly described; (2) that these races are so mixed at the present day that representatives of them appear not only in most European nations, but in the same families, and among children of the same parents; (3), that notwithstanding this mixture, and the effects which it must permanently have, racial character displays an astonishing permanence; (4) that this mixture, being so slow in its effects, and yet having become so general, has probably been at work, and for a very great length of time, so great that the peoples to whom the earliest history of Europe introduces us were probably nearly as much mixed as those of the present day; (5) that it is desirable to discontinue the use of the political names of those people as ethnic names, and to employ others based on the physical characteristics of the individuals; (6) that while physical characteristics are the only basis for a true division into races, yet in any practical application of this division, we must consider the influence upon individuals of different races of a community of language, whose history or tradition must not be lost sight of, although these things do not prove community of race, but only the contact at some time or other of the races to whom they are now common.

Prof. Huxley said the subject of the paper was one of importance, not merely on ethnological or scientific grounds, but because it was unfortunately the source of a great many practical fallacies which have had, and in fact still have, a very important political influence. He doubted very much whether there was any deliberate system of misnomer which was working more mischief in this world than the preposterous talk about the national qualities of the Celt and the Saxon. He had taken the liberty a number of years ago of getting himself into hot water by trying to awaken people's attention to what was the effect with regard to the use of these terms, and to the sort of mischief that was

being done by using them in the exceedingly inappropriate manner in which they were naturally used by political writers. His conclusions then were entirely in accordance with those which Mr. Lewis had just now brought before them. He (Prof. Huxley) believed that if there was a proposition in ethnology which was capable of historical proof it was that, so far as physical characteristics were concerned, the ancient Gauls—as was the opinion of the Roman and Greek historians—were persons of precisely the same physical peculiarities as the ancient Teutons known to the same historians. In fact, there was a most extraordinary correspondence to the phraseology in which the Teutons are described by a well-known writer, and those in which the earlier historians described the Gaulish invaders of the Roman Empire and the Greek Kingdom. That he believed to be beyond all question, and so far as physical characteristics went, he did not believe that there was a shred of evidence to show that the persons who spoke Celtic dialects at the time they made their appearance in Western Europe were in any physical respect different from those who spoke the older Teutonic dialect, and not only that there was no difference, but there was a most extraordinary resemblance, inasmuch as those stocks when they came into contact with the civilised world were described in the same terms—as sturdy, fair-haired people, with fair skins, and what he thought without any exaggeration may be described as a remarkable shortness of temper. He would not enter now into the interesting questions which Mr. Lewis had raised. The deliberate conclusions which were drawn from this subject with regard to the real distinction of race in our islands were, that the people of some particular race were marked by a tendency to certain social organizations and certain peculiar mental constitutions. Now he dared say that might be so. He could not—no person who was a professional zoologist could—fail to entertain the most exalted ideas of the influence of race, and he had no doubt there was great influence; but what he did very much doubt was whether they had the smallest means of knowing what at the same time was the amount of influence exerted on the people of this country by the different ethnological elements which compose it. Let any one who listened to the talk about national characteristics, and what was said about particular institutions being impossible for some of the people of these islands and possible for others—let him carry his mind back for the last twenty years and think what was at that time said about the German people. Great writers of public opinion at that time were never tired of enlarging on the saying of one great German, that while the Empire of France was on the land, and that of the British on the sea, the Germans had the empire of the air; but they proved themselves during the last fifteen years to be about as practical and hard-fisted a people as any that existed at the present time in the universe; and we did not hear anything of the Teutonic dreamers since the battle of Sedan. He believed that we knew so little about the races that it was impossible to disentangle what any particular nation was. We did on the other hand, know that there was a great deal of human nature in all kinds of men, and of social conditions which exercise an enormous influence. He thought he would endeavour to make out what in any given race at the present time was due to the pre-existing social and political relations—and when he had sifted that he would have some reason to talk of *residuum* as being the consequence of race influence. He himself did not believe, taking any one section of the British empire—whether Scotch or English or Irish—he did not believe that race has any appreciable influence upon their social and political condition of the present day. That was to say, his impression was that if the south-eastern parts of the British empire, the county of Kent for instance, had been subject to just the same sort of conditions for 400 or 500 years as, he would say, Connemara and Galway, he should expect the results to be as nearly as possible the same; and it was a curious fact of ethnological study that those parts of Ireland which are supposed to exhibit in the most marked manner these characteristics, sometimes complimentary and sometimes uncomplimentary, were those in which it could be proved to demonstration that the Norman and English elements were most predominant.

Captain R. F. Burton read a paper entitled *Notes on the Tribes of Midian.*—The country once belonged to the Moabites, Ammonites, and Amalekites of Scripture, but the tribes now inhabiting it were comparatively modern. They were a mixed race. The inhabitants of the uplands were fairer in complexion and more fleshy and muscular than the dwellers in the lowlands, who were more dark and slender. Some of the higher classes were decidedly handsome, having erect muscular figures, straight features, black hair, and olive-coloured skins, fine eyes, restless and piercing, though their beards were rather thin. Longevity was rare amongst them in consequence of incessant fatigue, indifferent nourishment, and want of cleanliness. The inner man was not so easily described. Their chief characteristics were strong social affections, eternal suspiciousness, extreme pugnacity, and proportionate revengefulness. Their sociability was extreme, and they made great sacrifices for one another.

Prof. W. H. Flower read a paper *On the Methods and Results of Measuring the Capacity of Crania.*—Of all the measurements by which they could determine the difference between the human skulls of people of one race and of a foreign race, perhaps the most important was that which gave the cubic capacity of the great cavity of the skull which contained the brain. Many ways of ascertaining it had been tried. Some persons laid great stress on the weight of the brain, but for his part he thought that on the whole if the capacity of the skull could be got it would be more valuable. The weight of the brain differed very much according to the age or physical conditions of the person when he died, and there were certain diseases which went to increase the specific gravity. But when the actual capacity of skull was found they had the actual capacity of the brain at the time of health. There was another very important reason why they laid stress on obtaining the capacity of the crania in preference to the other method. It was because all their museums now contained a number of skulls from different parts of the earth, some of which were very inaccessible to scientific observation, and it was, of course, impossible to ascertain the actual weight of the brains of these people after death. Then, again, how could they get the capacity of the skull by the weight of the brains in cases where the races had become extinct, such as the Tasmanians, many of the Polynesians, the ancient Britons, and the ancient Irish, and others, specimens of whose skulls they possessed, and by which they could ascertain the capacity of the brain? He supposed he would be expected to say at once whether he attributed any great and direct importance to the weight and age of the brain as an indication of intelligence. Well, he thought it was one of the very many points that had to be considered in this question; but he thought there were a great many other things to be remembered in this view of the question. For instance many people had large brains and did not know how to use them, and some who know how to use them did not try to do it. They would see that many of the races that were naturally considered the higher races, and had taken the lead in the civilisation of the world, had undoubtedly larger cranial capacities than the peoples who were at the bottom of the ladder of civilisation. He would never accept the mere fact of a man's head being large as an indication of superior intelligence, but it was one point to be considered. The measurement of the skull was not only an important but it was also a difficult work, more difficult in fact than a great many people supposed, and a great many of the uncertain results that had been obtained on this subject were owing to the persons who had taken the matter in hand not having yet discovered the best and most certain method of carrying out the investigation. A large number of measurements published were only of an approximate value, owing to the numerous fallacies and difficulties experienced in arriving at a satisfactory method of measurement. Nothing, apparently, could be easier than to take a skull and stop the cavities, and pour some fluid into it and then pour it out and measure it, but they could not do this with the skull, as the bone was very porous and full of minute invisible holes, through which the fluid soaked as it would through a sponge. It was only by making the skull waterproof that they could seek to measure its cavity by a fluid. He had a skull by him which had been so prepared. The large holes had been filled with wax and the skull soaked in melted paraffin, which filled up the minute cavities, and when it was cooled it was as impervious to any fluid as delf. But the materials that had to be used in testing the capacity of the skull must be something solid. Various things, such as shot, grain, &c., had been used. He would pass over the various methods that had been tried and failed, and which would be found recorded in the *Transactions* of the Anthropological Society of Paris, and speak of two methods which at the present time meet with the greatest amount of success. One was the method of Mons. Broca, and the other the method of Mr. Busk. The latter had shown such good reasons for his plan that he thought it particularly safe to try it, and after doing so he had adopted it with some modifications.

He filled the skull with mustard seed well shaken, and pressed into it with the thumb, and then poured into a long wooden box with glass sides in it, in which it was well shaken and pressed down. The figures on the glass indicated the spaces filled. This he thought was the most satisfactory way as yet invented, and they could hardly hope for better. He always kept his experimental skull by him when measuring other skulls, in order that he might occasionally go back on it to see if he had gone wrong. Now, as to the measurement of the skulls of the different races of the human family, a very important point to consider, and a very difficult one, was the sexes, because there was a great difference in the size of the skulls; a much greater difference than there was between men of different races. To get the average of any race they must get a large number of skulls, and he must say their collection was very insufficient at present. According to a comparison between the skulls of sixty-three men of various races, and skulls of twenty-four women, the size of the woman's skull to the man's was as 854 to 1,000. The largest normal skull he had ever measured was as much as 2,075. He knew nothing of its history. It might have been the head of a great philosopher, but unfortunately they were not in the habit of getting the heads of philosophers in their museum. Nearly all the English skulls were those of persons in the lowest ranks of life. It was these they had to compare with the specimens of other races. The smallest head he had measured was 960 centimetres, and that belonged to one of those peculiar people in the centre of Ceylon, who were now nearly extinct. The largest average capacity of any human head he had measured was that of a race of long, flat-headed people on the West Coast of Africa. The Laplanders and Esquimaux, who were a very small people, had very large skulls. The latter gave an average measurement of 1,546. He then came to the English skull, which was nearly the same size—1,542; but, as he had said, they belonged to the lower grades of English skulls. He could not tell them anything about Irish skulls, for there was not a single specimen of the Irish skull in any London museum. The inhabitants of the Canary Islands give a capacity of 1,498; the Japanese, 1,486; the Chinese, 1,424; the modern Italian, 1,475; the ancient Egyptian, 1,464; the true Polynesians, 1,454; negroes of various kinds, 1,377; the Kaffirs, 1,348; Hindoos, 1,306. They then came to the Australian aborigines, who were amongst the smallest, only giving an average of 1,283. There were two races still below the Australians, namely, the Andamanese, who were a very diminutive people, with a capacity of 1,220, and the Veddahs, of Ceylon, who had an average skull.

The President (Prof. Huxley) said he might, without hesitation, offer the best thanks of the Section to Prof. Flower for the important and interesting paper he had just read. Persons not ordinarily occupied with scientific pursuits might not be aware of the amount of care that had to be taken when it was desired to do any good in scientific matters in obtaining data, which data would, when obtained, pack into the very smallest possible results. It would be seen what care was required to obtain measurements of the cubical contents of the skulls, and yet the whole of the labour, if Mr. Flower published his paper, as he hoped he would, would go into the space occupied by the three or four rows of figures. There was one very interesting question he wished to put to Mr. Flower—whether it was possible to establish not only a series of absolute measurements of the capacities of the skull, but also some kind of index of capacity in which can be expressed the ratio of capacity of the skull to the stature of the person to whom it belonged, or if it was impossible to obtain that, yet even to obtain such data as would show the relation between the contents of the skull and the length of the part of the skull which was, as it were, the foundation of the skull.

Department of Anatomy and Physiology.

On a Direct Method for Determining the Calorific Power of Alimentary Substances, by J. A. Wanklyn and W. J. Cooper.—The amount of oxygen consumed by an organic substance being the measure of its heat-producing force, the importance to physiologists of a direct and rapid method for measuring the consumption of oxygen in organic fluids is obvious. It is well known that an elementary combustion will effect this object, but, as is likewise well known, the great difficulties which beset it render it unavailable for physiological researches. The process by which we obtain all the results of an elementary combustion can be completed in about an hour, and in the course of our experiments on various organic substances we have been enabled to get an amount of oxygen absorbed which is equal to the theoretical quantity required by the substance operated upon. In point of fact, we have so modified Forchhammer's process as to make it work in a satisfactory manner.

Forchhammer's process, as hitherto practised, does not effect anything approximating to complete oxidation down to carbonic acid and water, as was illustrated by some experiments published by Frankland and Armstrong in 1868 (*vide* Chem. Soc. *Journ.*, vol. vi. p. 82), which we quote:—

Name of substance (30 parts dissolved in 1,000,000 parts of water).	Oxygen absorbed during six hours.	Oxygen required for complete oxidation.
Gum arabic	0·35 ...	35·5
Cane-sugar	0·15 ...	33·7
Starch	0·30 ...	33·5

showing that, as usually carried out, the oxidising process does not avail to accomplish more than about one-hundredth part of the task set before it.

The modifications whereby we have completely altered the character of the Forchhammer process are as follows:—

Instead of simply mixing the standard solution of permanganate with the water to be examined, we *distil* a given volume of the water (say 1 litre) with a considerable excess of standard solution of permanganate, and thereby get more oxidising action than in the ordinary operation. We find advantage in having the liquid strongly alkaline during the distillation; but we render it acid before titrating the residue.

Mr. Lawson Tait, F.R.C.S., read a paper entitled *Note on the Occurrence of a Sacral Dimple and its Possible Significance*.—Some years ago he noticed casually the occurrence of a curious pit-like depression or dimple in the skin over the lower bones of the sacrum amongst the patients of the hospital for women to which he was attached. He paid no special attention to it until about two years ago, when an instance came under his notice of a woman in whom it was well marked, and in all of whose children it was to be observed. Three of them, all girls, had it strongly pronounced; and in one, the eldest, about eight years of age, he found the best marked instance he had yet seen. It was quite a centimetre in depth, and it expanded outward, so that its mouth had a diameter of about 13 millimetres. This circumstance induced him to make observations as to the frequency of its occurrence in some hundreds of women passing under his notice, and he found that in 55 per cent. no trace of it was visible, that in 22 per cent. it was faintly marked, and in 23 per cent. it was well marked. Occasionally two depressions were present instead of one, both being in the middle line always, and situated from half an inch to an inch and a half apart. The average age of the women, in whom it was well marked, was slightly over 32 years, whereas that of those in whom it could not be observed was nearly 45, from which he concluded that it had a tendency to disappear with advancing age. The same inference was to be drawn from observations made by Dr. A. H. Carter at the Children's Hospital. The prevalence of this curious mark was suggestive that it must be a remainder from some embryonic process connected with the neural canal and its closure. The explanation which he was about to offer of its significance must be viewed charitably, and as the result of an accidental observation. Mr. Tait then gave an account of the appearance presented by the body of a kitten remarkable as having no tail. The mother was a favourite cat in a district where there were no tailless tom cats. The lady who presented it to him told him that during the whole of the kitten's brief life water was seen to run from the spot where the tail ought to have been, which water was industriously removed by the mother. The kitten took nourishment, and moved about after the fashion of new-born kittens, but did not appear to use its hind legs. On examining the body he found a small aperture through which fluid could still be pressed, and on opening this carefully he found that it passed through a deficiency of the neural arches of the sacrum, directly into the cavity of the spinal cord. At this point the cord broke up into its ultimate branches, and the tail was represented just as it is in other tailless vertebrates, the neural arches being inclosed, and the caudal vertebra being represented by only three elongated centra, enveloped in a slight fold of skin, just as in the Manx cat and in the Guinea pig. The study of a number of human sacra revealed the

curious fact that they differed very materially. The sacrum is generally figured as being composed of five vertebral elements, but he had frequently found six, and in one case seven. A friend had told him that he had seen one with only four. Of the five usual sacral vertebræ the two lower are generally figured as having gaps in the neural arches, but it was his experience that it was more usual to find the gap also in the third, and he had seen sacra in which there was only one neural arch. He had not studied the sacra and coccyges of any of the tailless vertebrata but the guinea pig, but even in it he had found curious variations, chiefly in the length and number of the coccygeal centre, and he assumed that in such an early type such variations must of necessity be less marked than in the later ones. He thought it likely that spina bifida was not confined to the human animal. In the human animal its most common seat is the sacral and lower lumbar vertebræ. It was fair to assume, therefore, that in a tailed vertebrate it would occur more frequently in the tail than elsewhere. If this be the case, and if, likewise, it ever does occur amongst animals not domesticated, it will most certainly occur occasionally that a tailless vertebrate will, by reason of a spina bifida, be born of properly tailed parents. If the deformity was sufficiently high up to destroy the tail, yet not high enough to interfere with the nervous supply to the posterior limbs, then he might survive in the struggle for existence, provided the tail was not essential to life. They could easily imagine that under favourable circumstances a monkey born with this change in his economy might strike out a new line of life, breed tailless children, and by the change of other structure necessitated by the new method of life, introduce a new variety of monkey. Those who were still opposed to the evolutionary view of creation might sneer at this as a series of "ifs," but they must be reminded that the whole of life—individual and collective—is but a change of circumstances, precedent to any one of which an "if" can be introduced, and that had "if" really been effective the whole chain would have been different from that point. What, then, was the significance which might be attached to the sacral dimple which was the subject of the paper? Looking at it surgically there could be no question that it was a cicatrix. What he ventured to suggest was that it was the hereditary cicatrix of the *spina bifida* by which the human tail had been lost. Such a suggestion was of course open to ridicule, but only, he ventured to think, in the minds of the incautious or the ignorant. That man was once a tailed vertebrate was beyond doubt, and that he lost his tail was, of course, equally evident. He was not the only vertebrate who had lost a tail, and in whatever way those tails had been lost they had evidently all been lost in the same way. Now, curiously enough, they had an animal living in one of the sister isles of which not a genus, nor a species, nor a variety, but a mere family had lost its tail; he referred of course to the Manx cat. He had obtained some of these cats from the Isle of Man, and he was quite certain that if they knew the history of this curious family of cats they should know exactly how all the vertebrates which are now tailless became so, and he felt very confident that the Manx cats lost their tails through the occurrence, within very recent times, of a tom cat with a *spina bifida* placed exactly where it was in the case of the kitten he had referred to. A limited area like Man would present the most favourable circumstances for the protection and propagation of such a variation; for he (Mr. Tait) had already elsewhere pointed out that the bushy tail of such animals as the cat served chiefly for the purpose of maintaining temperature, and in the mild and equal climate of the charming island a tailless cat would have little hardship to endure. It could not have survived, however, in any place where snow lay long on the ground. In the few Manx cats he had examined he had seen no trace of dimple, nor had he seen any appearance of it in the guinea pig; but these negative results did not seem to him to be important. What would be important would be the examination of a number of tailless monkeys, especially young ones. If in these no dimple was to be found, then he feared they should have to look forward to some other history for this curious cicatrix.

The president said he was not inclined to take the same view as Mr. Lawson Tait as to the means by which the tail in the human species had been got rid of. It appeared to him that what Mr. Tait had described was more likely to be the remains of infantile *spina bifida*. It was all very well for human beings to object to their having tails, but, as a matter of fact, they had tails, though they had disappeared to very small dimensions, in which they now existed in the human family.

Department of Zoology and Botany.

On the Remains of a Permian Fauna in North America, by Prof. E. D. Cope, U.S.A.—Prof. Cope described the remains of a fauna, now extinct, which had inhabited North America during the period of geologic time next succeeding the coal measures, which is known as the Permian. He had first ascertained its existence through specimens sent from Illinois in 1875, but had discovered much larger deposits of similar animals in Texas. The characters of the latter showed that they were to be referred to the classes *Reptilia* and *Batrachia*. A number of generic types of reptiles were mentioned, most of which are characterised by the notochordal vertebræ. He particularised the characters of the dentition of *Diadectes* and *Bolosaurus*, where the teeth are transverse to the long axis of the jaws. He entered more fully into the structure of *Clepsydrops*, Cope, where almost the entire skeleton had been discovered. This includes clawed lizards, with large canine teeth and several incisors, humerus without condyles, but with supracondylar foramen; reptilian posterior limb; boat-shaped pelvis, without obturator foramen, and with the neural spines of the sacral vertebræ greatly elevated (in *C. natalis*). There are small intercentra between the inferior parts of the adjacent centra, which support the chevron bones in the tail.

The Batrachia display remarkable characters of the vertebral column. In *Cricotus* the intercentra are developed so as to resemble centra, so that the column appears to consist of two kinds of vertebræ alternating with each other. A neural arch of the caudal series stands equally on centrum and intercentrum, but the intercentrum only bears the chevron bone.

Sir J. Lubbock read a paper *On the Habits of Ants*.—The author observed that he had kept about thirty species of ants in confinement. They throve well, and he had some specimens which he had kept since 1874. They were probably bred in the previous year, and would now, therefore, be five years old. He also referred briefly to the other insects which were kept by ants in their nests, and especially to aphides, some species of which are kept and carefully tended by the ants throughout the winter, though at that season they are not of any use. He referred shortly to his experiments on the senses of ants. Their sense of smell is very delicate, though much more so in some species than in others. On the contrary, he had never observed any proof that they are capable of hearing. As regards sight, he had been able to satisfy himself that they were capable of distinguishing colours, and that they are, for instance, very sensitive to violet. The ants of a nest not only knew one another, but they remembered one another even after a year's separation; and he recorded some experiments by which he attempted to ascertain how the recognition is effected. He also referred briefly to the insects which are domesticated by ants, and gave a short account of the slave-making species, which are (at least in one case) entirely dependent on their slaves, and would perish even in the midst of plenty if left to themselves. He kept some of these ants, however, alive for months by giving them a slave for an hour a day to clean and feed them. The communities of ants, he said, offer numerous analogies to those of men, and the difference in the habits of the various species of ants are also in this respect not without interest. The slave-making ants, indeed, represent an abnormal and, perhaps, only a temporary state of things, for it is not impossible that the slave-making species will eventually find it impossible to compete with those which are more self-dependent and have reached a higher phase of civilisation. But putting these species on one side, we find in the different species of ants different conditions of life curiously answering to the earlier stages of human progress—namely, the hunting and pastoral, and even to the agricultural. For instance, some species, such as *Formica fusca*, live principally on the produce of the chase, for, though they feed partly on the honeydew of aphides, they have not domesticated these insects. These species probably retain the habits once common to all ants. They resemble moreover the lower races of men who subsist mainly by hunting. Like these, they live in comparatively small communities, and the instincts of collective action are little developed among them. They hunt singly, and their battles are single combats like those of early history. Such species as *Lasius flavus* represent a distinctly higher type of social life. They may literally be said to have domesticated certain species of aphides, and may be compared to the pastoral stage of human progress, to the races which live on the produce of their flocks and herds. Their communities are more numerous, they act more in concert, their battles are no mere single combats, but

they know how to act in combination. Sir John was disposed to hazard the conjecture that they will gradually exterminate the mere hunting species, just as savages disappear before more advanced races. Lastly, the agricultural nations may be compared with the harvesting ants, none of which, however, live in our country. When he first began keeping ants, Sir John surrounded the nests by moats of water. This acted well, but the water required continual renewing, especially of course in summer, just when the ants were most active. At length, however, in considering the habits of ants and their relation to flowers, another plan occurred to him. The hairs by which plants are clothed are of various forms, and fulfil various functions. One is to prevent ants and other creeping insects from climbing up the plants so as to obtain access to the flowers, and thus rob them of their honey. It occurred to him, therefore, that instead of water he might use fur, arranged so that the hairs pointed downwards. This he found to answer perfectly; and he mentioned it specially because the same arrangement may perhaps be found practically useful in hot climates. It is, of course, very possible, indeed, that the tropical species might be able to climb up the fur, or that for other reasons the plan might fail—the fur itself, for instance, might be devoured—but, at any rate, the experiment would be worth trying. It is generally stated that the queens alone lay eggs. This, however, appears not to be the case. The workers do sometimes, though only as exceptions, lay eggs; but it is curious that their eggs always appear to produce males.

Sir Walter Elliott made a few observations *On the Annual Increase of the Common Vole* (*Arvicola agrestis*) *of late Years.*—In the spring of 1876 they appeared in such numbers in the hill pasture farms of the border districts between England and Scotland, and parts of Yorkshire and Wensleydale, as to destroy the grazing ground on which the sheep depended in spring, causing serious loss to the farmers by impoverishment and death of stock.

Dr. R. H. Traquair read a paper *On the Genus Ctenodus* (Agassiz).—The object of the paper was to suggest the great probability of the identity of the genus Campylopleuron of Huxley with Ctenodus of Agassiz. Should that be the case, Ctenodus will differ more from the old red sandstone genus Dipterus than is usually supposed, as in Camplyopleuron there is, as in the recent Ceratodus, a continuous dorsocaudal fin.

Aberrant Sacrum connected with the Oblique Pelvis.—Dr. Allen Thomson, F.R.S., showed a number of sacra exemplifying the irregularity which he regarded as the cause of oblique pelvis. He referred to similar developmental irregularities occurring in the lower animals, and exhibited one specimen—namely, the skeleton of a wombat—where the irregularity was one-sided, as is the common cause of the oblique pelvis in the human subject.

Prof. Macalister, Dr. Lawson Tait, and Dr. Harvey took part in the discussion, and all the speakers agreed that the developmental cause must be considered the usual one, and in ignoring the occasional occurrence of this form as resulting from disease.

Mr. R. W. Sinclair read a paper *On Recent Additions to the Irish Lepidoptera.*—In his paper he mentioned fifty-four species new to the Irish list. Mr. Sinclair said that it was very remarkable that of the large number of fen and marsh insects that occur in England, hardly one-third occur in Ireland; for instance, in the genus Leucanidæ, out of the thirty-one English species only thirteen are Irish.

Mr. C. Spence-Bate, F.R.S., presented a report *On the Present State of our Knowledge of the Crustacea.*—This paper formed Part 4 of the series, and was on development. Mr. Spence-Bate also read a paper *On the Willemœsia Group of Crustacea in the "Challenger" Collection.* These had all been stated to be animals without even the rudiments of eyes, and appeared to correspond very closely with the genus described from the Mediterranean as Polycheles. The author pointed out that not only were the animals of the group not blind, but that they had eyes of varying proportions. The species of these genera were taken at thirteen different stations, at depths varying from 120 to 1,900 fathoms, and chiefly on a soft bottom of mud or globigerina ooze, and he thought they might safely infer that the entire group are dependent upon the nature of the bottom for their existence, and that their general form is in accord with the habits of an animal that burrows in the deep sea ooze, which has been selected as its best adapted food.

Mr. H. H. Howorth, F.S.A., read a paper *On the Extinction of the Mammoth in Siberia*, the principal object of which was to deal with the difficulties that surrounded the explanation as to the mode in which the animal became extinct. After looking at the problem from every side, he had come to the conclusion that there had been a sudden and violent change of climate in Siberia which had frozen the previously soft ground, and had also preserved the mammoths as in a huge meat safe. Although the mammoth had even originally lived in the place where he was now found, it was impossible that he could live there now, owing to the absence in that part of the food which would be necessary to sustain him. Such trees as he used to live on were only now to be found about 500 miles from the spot where his remains were discovered. The natural corollary that followed from this theory was that something similar must be postulated with regard to other regions. The conditions in which the elephant was found in Siberia were precisely similar to those in which it was found in the north-western part of Russian-America, and precisely the same as those in the Great Lakes, where the mammoth itself was found, and it could not, therefore, be doubted that the mammoth lived in Europe and America with the same food and surroundings as it did in Siberia.

SECTION E.—Geography.

Captain Burton read a paper *On the Land of Midian*, giving an account of his recent explorations in that region, which have already been referred to in these pages.

Dr. Phené read a paper *On the acquisition of Cyprus, and Observations on some Islands in the Levant with Reference to Recent Discoveries.* The author, who had recently made a prolonged and careful voyage of research in the Levant, described the physical features of the islands of Chios, Mitylene, Lemnos, Imbros, Thasos, and Samothrace. He selected Samothrace for ascent, and was, so far as he could learn on the island, the only European, not being a native, who had made the ascent, which was very difficult. The height was slightly over 5,000 feet. The climates, culture, and salubrity of the different islands were dwelt on. Cyprus had a variety of climate, so that the debility produced by the heats in the south could be relieved by a retreat to the northern coast, which was cooled by the breezes coming from the Karamanian Mountains, while in some inland parts were rich woods abounding with game and objects for the chase.

Major Wilson, Director of the Ordnance Survey of Ireland, also read a paper *On Cyprus.*

Lieut. Kitchener, R.E., in a paper *On a Survey of Galilee*, gave an account of the progress of the work of the Palestine Exploration Fund in that region. The great work on which the Society has been employed for the last six years, is a map of Palestine on the model of the Ordnance Survey of England and Ireland. The map of Palestine on the one-inch scale has now been completed. Lieut. Kitchener then detailed the progress of himself and his predecessors in the work of surveying and in exploring ancient remains and sites. At the end of this year, if funds are available, an expedition will start to explore the sites of the most sacred scenes of the New Testament history—the northern shores of the Sea of Galilee, where undoubtedly Capernaum, Chorazin, and Bethsaida still exist. In addition to this the expedition will make a thorough survey of the unknown country forming the eastern shores of that sea, on the same scale and with the same accuracy as the present survey. They hope also to rescue from the hands of that ruthless destroyer, the uneducated Arab, one of the most interesting ruins in Palestine, the Synagogue of Capernaum, which is rapidly disappearing, owing to the stones being burnt for lime.

Mr. W. H. Dall, of the U.S. Survey, gave an interesting account of its recent exploration in Alaska, some of the results of which we have referred to in Nature.

SECTION F.—Economical Science and Statistics.

A paper by Prof. Jevons was read *On the Periodicity of Crises and its Physical Explanation.*—Various reasons, such as wars, trades unions, luxurious living, &c., had been given as explanations of the now constantly recurring depression of trade. Such explanations he (Prof. Jevons) did not consider satisfactory. Depression of trade had occurred during the present century with remarkable regularity at intervals of ten years. Sir John Herschel had attempted to find a connection between certain meteorological phenomena and the price of corn in Europe. If we traced backward from 1866, when a very great depression of

trade took place, it was to be observed that in 1857 an equally severe commercial crisis took place both in England and the United States. The year 1847 was memorable for the excessive number of bankruptcies, and in 1839 and 1836 crises took place in England, while in 1837 the crisis took place in the United States. Some exceptional cause appeared to have broken up the crisis into minor crises. From 1837 they progressed 11 or 12 years to the great bubble year, 1825. The paper went on to show that during the last 165 years there had been 16 great commercial crises at intervals of about ten years and concluded by stating that the fact of periodicity of commercial crises was so strong that it could not be doubted, and the question of a physical cause was only a matter of speculation.

SECTION G.—MECHANICAL SCIENCE.

Mr. G. J. Symons, F.R.S., read a paper *On the Rainfall of Ireland*, in which he mentioned as a remarkable fact that the Irish hills do not exhaust rain clouds as the English hills do. With the exception of a dry central area around Dublin, the rainfall all over Ireland may be taken to be the same. At present, instead of the greatest rainfall being in the south-west, or in Galway, we have the wettest spot of all (with one exception) in the south of the county Down, the very place which, theoretically, might be expected to be almost the driest part of Ireland. That shows that it is really a question more of the elevation of hills than of geographical position. He exhibited a map showing the number of rain stations established for the observation of the rainfall. He had succeeded since the meeting of the Association in Belfast in obtaining the services of a large number of gentlemen volunteers throughout Ireland who had taken charge of the rain-gauges supplied to them, and had engaged to register their observations. There were still large districts, however, in which he had not been able to establish rain-gauges, and the observations were, therefore, necessarily defective as to the average rainfall. There was a large district in the neighbourhood of Longford without a single station. The same could be said of other stations, where it was essential that observations should be taken. If he could induce some gentlemen having property in these neighbourhoods to take charge of rain-gauges, Ireland, instead of having to depend upon ten stations, as it did not many years ago, would be fairly represented both geographically and physically.

Mr. W. H. Preece, C.E., read a paper *On Recent Advances in Telegraphy*, with the effect of showing that improvement in telegraphy was never more active in England than it has been since the Government managed the business. Having indicated the improvements effected, the paper concluded :—"The control of Parliament and of the press exercises a far more disciplinary and supervising power on the management of a Government department than any half-yearly meeting of shareholders, or occasional committee of investigation."

Mr. Wigham read a paper *On the Irish Siren Fog Signal.*—The Irish siren is adapted either for steam or compressed air, and differs from those made in America and in England in being driven by a species of small turbine actuated by the current of the steam or air by which the instrument is sounded, the rate of rotation being controlled and rendered uniform by a simple governor, a much less complex arrangement than the somewhat cumbrous mechanism which has heretofore been used. The Irish siren is applicable to steamships as well as to lighthouses.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

PROF. HELMHOLTZ is succeeded in the rectorship of the Berlin University by Prof. Zeller.

THE University of Halle is receiving valuable additions in the form of new edifices for the various departments. The necessity of new buildings with modern appliances has long been felt, and the want is being met at present by the erection of a library, two new clinics, and pathological, physiological, and anatomical institutes.

SWEDEN possesses at present one of the most thorough systems of education in Europe. It is difficult to find a district where one per cent. of the population are unable to read and write. The common schools of the country cost about 220,000*l.* yearly. There are numerous institutions for agricultural and technical education, and two universities at Lund and Upsala, which compare fairly with the German universities, in regard to the amount of valuable research carried out in various departments.

SPAIN has at present ten universities. Those of Madrid, Barcelona, and Granada possess each five faculties—law, medicine, pharmacy, the exact sciences, and philosophy and literature. In those of Salamanca, Seville, and Valençia pharmacy is absent. Saragossa has law, medicine, and philosophy; Santiago and Valladolid law and medicine; and Oviedo law only. The professors number 414, and the students 15,000; Madrid alone contains, however, 76 professors and 6,500 students. Technical education is provided for by schools of mines at Madrid and Almaden, the agricultural schools of Madrid and Cordova, the veterinary institutes of Madrid, Cordova, Leon, and Saragossa, the School of Architecture, and the school of Civil Engineers at Madrid, as well as polytechnics in various cities. Preparatory schools number 63, with 30,000 students, and elementary schools number 28,000, with an attendance of 1,400,000.

SCIENTIFIC SERIALS

American Journal of Mathematics, vol. i. No. 2.—On the application of the new atomic theory to the graphical representation of the invariants and covariants of binary quantics, by Prof. Sylvester.—Researches in the lunar theory, II., by G. W. Hill.—Bipunctual co-ordinates, by F. Franklin.—Desiderata and suggestions. No. 2. The theory of groups; graphical representation, by Prof. Cayley.—On the electric potential of crystals, by W. E. Story.—Théorie des fonctions numériques simplement périodiques, by Prof. Ed. Lucas.

THE ZOOLOGICAL RECORD

The Zoological Record for 1876; *being Volume Thirteenth of the Record of Zoological Literature.* Edited by Edward Caldwell Rye, F.Z.S., &c. (London: 1878.)

ANOTHER volume of this useful annual is now before us. When, about a twelvemonth since, we noticed (NATURE, vol. xvi. p. 357) its predecessor, we took occasion to complain of the ingratitude of zoologists in not giving more efficient support to a work which, if not indispensable to the due prosecution of their studies, would at least lighten their labours in a remarkable degree, and we pointed out how it was a matter of obligation upon all literary and scientific institutions to include the *Zoological Record* among the books they regularly purchase. We fear that our words fell upon dull ears, and that there is as much need now as there was then to impress these considerations on the public. The Zoological Record Association, to judge from its recent balance-sheet, still lives upon charity, to the great discredit of the zoologists of our own tongue as a body, and if its existence be prematurely brought to a close, it will be to their everlasting disgrace. In some respects the energy of zoologists is boundless, in other respects their apathy is amazing. They will compass sea and land to gain one new specimen for their collections, or one apparently new species for their monographs. They think themselves happy in the short-lived glory of being able to inscribe "*Nobis*" or "*In Mus. nostr.*" after its name in some printed list; but they care very little to know what others are doing in the same line of research, and when a few years after, some industrious German or Scandinavian naturalist quietly relegates the name on which they had plumed themselves to the limbo of synonyms (perhaps with a mark of admiration which does not mean praise), they accept the rebuff and console themselves with the reflection that "a fellow can't be expected to know everything," or, if twitted by a friend, will ask in an aggrieved tone whether it is possible for anybody to be acquainted with the contents of two hundred foreign journals. Then, again, there is the obstacle caused by dislike to, or suspicion of, any new thing, from which even scientific men are not entirely exempt. The conchological investigations of Mr. A. or the entomological studies of Dr. B., some thirty or forty years ago, conferred imperishable renown upon the ancient borough of Little Pedlington, in which they were both resident. Their investigations and their studies were accomplished without the aid of the *Zoological Record.* Therefore the *Zoological Record* is of no use to persons engaged in such labours, and therefore the Little Pedlington Literary and Scientific Institute need not go to the expense of adding the yearly volumes of the *Zoological Record* to its bookshelves. Perhaps some of our readers may smile, but we believe this to be no uncommon case, and though the sight of a just man struggling with adversity is said to have been pleasant to the gods of old times, we cannot say that the condition of the Zoological Record Association awakens similar feelings in ourselves.

Now as to the present volume. With the same contributors as the last, it has naturally almost the same qualities; but the editor has introduced a new feature in the separate pagination of many of the records. This scheme has been tried, he tells us, in the hope of saving time, but the very insignificant amount of delay which it seems to have avoided, appears to us but a poor and utterly inadequate recompense for the additional trouble there always is in citing a book so paged, and the amount of confusion to which this manifold system invariably gives rise. Here we have page 1 fifteen times over, and yet one set of numbers runs to 240 pages! We certainly trust the editor will reconsider his determination of continuing this practice, though he holds out hope of its "possibly leading to other improvements." Otherwise we have not a word to say against Mr. Rye's management, which, as before, proclaims his great ability. We venture, however, to throw out a suggestion that perhaps may not be included among his possible improvements. This is that *general* works should receive a separate notice in addition to that which each individual recorder thinks fit to give them. The year 1876 will long be remarkable as that in which Mr. Wallace's great work on the "Geographical Distribution of Animals," appeared; but we must say that the attention it receives in this volume of the *Zoological Record* is utterly unworthy of the magnitude of the subject. Our readers shall judge for themselves. The recorder for *Mammalia*, Mr. Alston, after most properly naming it especially in his preliminary remarks, says of it:—

> "A considerable part of this most important work is devoted to the Mammalia. Besides the discussion of the genera characteristic of each of the zoological regions and sub-regions, the classification of Mammals is considered (i. pp. 85-90), the distribution of the extinct forms (i. pp. 107-160), and that of existing families and genera (ii. pp. 170-254). The author believes that the principal groups first appeared in the northern hemisphere, from which the southern continents were peopled by successive waves of migration."

The recorder for *Aves*, Mr. Salvin, writes:—

> "The class Aves supplies a large proportion of the material investigated in this work, and the distribution of birds entering into the subjects is examined under the the following heads:—(Part i.) The principles and general phenomena of animals. (Part ii.) On the distribution of extinct animals. (Part iii.) Zoological Geography: a review of the chief forms of life in the several regions and sub-regions, with the indications they afford of geographical mutations. (Part iv.) Geographical Zoology. a systematic sketch of the chief families of land animals in their geographical relations. The book itself is full of details most carefully elaborated, and is doubtless destined to be the standard work on the subject for some time to come."

The recorder for *Reptilia*, Mr. O'Shaughnessy, descants at greater length:—

> "The geographical distribution of the families and genera of Reptiles and Amphibians is treated collectively as a section, in chap. xix. of this work, vol. ii. pp. 392-423.
>
> "In discussing the means of Dispersal and Migration of the various classes of animals, Mr. Wallace remarks (vol. i. p. 29) that Reptiles, exclusive of serpents and sea-snakes, being scarcely more fitted than Mammals for traversing seas and oceans, are generally wanting in

oceanic islands which possess no indigenous Mammals; this rule is, however, subject to exceptions among the lizards, which apparently have some unknown way of passing over the ocean (probably in the egg state), as they are found to inhabit many islands where there are neither Mammals nor snakes. Snakes entirely cease at 60° N. lat., and at 6,000 feet elevation in the Alps. Lizards, though essentially tropical, go sometimes farther north than snakes, and ascend higher, reaching 10,000 feet in the Alps. Amphibians extend much farther north; Frogs to within the Arctic circle; their eggs are no doubt carried certain distances by aquatic birds, but salt water is fatal to them, and deserts and oceans constitute the most effectual barriers to their dispersal.

"Further remarks on the possible mode of transport of Reptiles to remote distances are made, vol. i. pp. 400-401, where the author treats of the points of similarity between the fauna of the Australian region and that of South America.

"Describing first in detail the faunæ of the six great geographical regions (Neotropical, Nearctic, Palæarctic, Ethiopian, Oriental, and Australian), the author refers successively to the Reptiles in their subordinate relation to each fauna, and afterwards, vol. ii. pp. 372-423, collects his results and tabulates them under the heads of the different families."

None of the other recorders seem to make mention of the work, except Dr. von Martens, who, under the head of *Mollusca*, contents himself with the following:—

"A. R. WALLACE gives an outline of the geographical distribution of the terrestrial (and freshwater) Mollusca in his 'Geographical Distribution of Animals,' vol. ii. pp. 512-529 and 534-535, and some instances of means for their passive dispersal, vol. i. p. 31."

Now we humbly submit that no adequate idea of Mr. Wallace's work is given by any one of these notices separately nor by all of them combined. As we said on the last occasion, we cannot find it in us to criticise the recorders, though they differ greatly (and this will be evident from the above extracts) in their mode of treatment. But in a case like this the editorial hand might surely be shown with advantage, and none can doubt that in a few sentences Mr. Rye, had his scheme allowed it, would have been able to put the reader in possession of Mr. Wallace's general principles and general results, while the different recorders would still be left to show how those principles and those results affect their respective branches.

It is, perhaps premature to say that the excellent plan of giving an index to the genera and sub-genera recorded as new, and of marking those names that had been bestowed before, has yet had the wholesome disciplinary effect that was expected of it, but there are indications that such is the case. The index to last year's volume showed that *fifty-nine* preoccupied names, implicating *thirty-seven* authors, had been reintroduced to zoological literature in the year 1875. The present volume shows the corresponding numbers to be *thirty-six* and *twenty-eight*—a manifest improvement, though not quite so great as at first sight appears, since in 1875 nearly a *thousand* new genera or sub-genera were instituted, while in 1876 the number is only about *eight hundred and seventy*. No one has again sinned as M. Mulsant did on the last occasion, but it seems strange that so learned an entomologist as Dr. Leconte should now head the list of offenders with *four* homonyms, and we suspect this must be due to a different reading of the laws of nomenclature which may obtain in America. Next to him come Messrs. Cope, Dybowski, Jacovleff,[1] Kirchenpauer, Linstow and Snellen with *two* each, and the rest with one. The selection of the same name, *Coptingis*, for two apparently distinct genera of *Erotylidæ* by M. Chapuis and the late Mr. G. R. Crotch, is curious, and the Arachnid *CorynEthrix* of Dr. Koch, and the Thysanurous *CorynOthrix* of Herr Tullberg seem to clash with one another. Collisions of this kind are, of course, unavoidable, but of the three dozen homonyms which come into the crop of 1876, a score-and-a-half might certainly have been avoided had their authors but followed the advice of Mr. Rye's motto:—

"Explorate solum: sic fit via certior ultra."

That is to say had they consulted their Agassiz's *Nomenclator* and used the *Zoological Record*.

It remains for us to say that the present volume contains an abstract of the zoological portion of more than two hundred-and-fifty distinct periodicals, besides separately published works, and that those journals hold a good deal hardly any one requires to be told. Nevertheless, it may be new to some of our readers to learn that papers which have appeared in the older volumes of many of these periodicals are in so much request that lists of them, with the proper pagination, are being reprinted. This has been done in the *Deutsche entomologische Zeitschrift*, by Herren von Heyden and F. Blücher, with regard to the entomological articles in the first sixteen volumes of *Der zoologische Garten*, the first thirteen of the *Verhandlungen des naturforschenden Vereines in Brünn*, four volumes of the *Bulletin de la Société des Naturalistes de Moscou*, and fourteen of the *Archiv für Naturgeschichte*. Trusting that next year we may be able to congratulate Mr. Rye and his fellow-labourers on having a more promising prospect before them, we bid them be of good cheer, for they have the sympathies of all who know how to appreciate hard and honest work.

OUR BOOK SHELF

Annual Report and Transactions of the Plymouth Institution and Devon and Cornwall Natural History Society. Vol. VI. Part II. 1877–78. (Plymouth: Bredon and Son.)

THIS Report seems to us to deserve more than the passing notice we gave it in a recent note on the Reports of provincial societies. The society embraces a wide range of work—science, history, archæology—and many of the papers which it publishes will compare favourably with papers of a similar class read in metropolitan societies. The society has a large membership, and valuable collections in various departments. In the Report before us the president, Prof. Anthony, discusses various interesting points in connection with the doctrine of evolution, and although he holds the theory to be "not proven," his discussion of the subject is fair. Mr. R. N. Worth, a great authority on most subjects connected with Plymouth, has papers on "The Palæontology of Plymouth," "The Early Commerce of Plymouth," a paper of much interest showing considerable research, and "The Ancient Heraldry of Plymouth." Mr. R. Briggs's paper on "The Hedgerows

[1] It is much to be wished that there were some recognised way of rendering Russian proper names into the languages of Western Europe. Germans, Frenchmen, and Italians, each render them phonetically, and of course the name is differently spelled according to the nation of the writer. Mr. Jacovleff's name thus appears also as Jakowleff, Yakovleff, and Jacovlev!

of Plymouth," is valuable and readable, containing the results of careful observation. "A Catalogue of the Geometrina of Plymouth and its Vicinity," by Mr. G. C. Bignell, will interest entomologists. "Our Obligation to Greek Thought," by Prof. Chapman, is a thoughtful paper, and there are several other excellent papers of historical and antiquarian interest.

Vulcanologische Studien. Von Dr. Eduard Reyer. (Wien: 1878.)

WE have already had occasion to direct attention to the valuable contributions to the theory of volcanoes which have recently been published by Dr. Reyer, of Vienna. The memoir before us fully maintains the reputation of its author as an able investigator and original thinker. In it he discusses the nature of the materials which remain in the throat and deeper portions of a volcanic vent, after the eruptive action has ceased, and the features presented by those volcanic cones which are formed not by violent explosive action but by the quiet outwelling of liquid lava. Dr. Reyer's remarks on both these questions will be found to be eminently valuable and suggestive. J. W. J.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Is the Sun One-sided?

WHEN Broun and Hornstein detected the existence of a terrestrial magnetic inequality, of which the period is nearly that of the sun's rotation, it was natural to regard this inequality as a direct result of the rotation of our luminary. Nevertheless, there are grave reasons against this hypothesis. In the first place, it is extremely difficult to imagine the sun to be one-sided in its magnetic influence. From what we know of our luminary, it must in a great measure be composed of gaseous matter, of which the outer layers are in violent motion, so that we can hardly imagine one meridian to be permanently different from another.

Another objection is derived from the fact that the period of this peculiar magnetic inequality (of whose existence there can be no doubt) is very nearly that of the sun's rotation in space, and decidedly less than that of its synodic rotation. Now, if we can imagine the sun to affect the earth in this peculiar manner, we should be inclined to suppose that the period of such influence would be that of its synodic rotation, that is to say, of its rotation with regard to the earth.

But if this inequality be not due to the sun's rotation, how (it may be asked) is it possible to account for it?

In the first place there is accumulating evidence of the existence of an intra-mercurial planet with a time of revolution, not differing greatly from that of the sun's rotation. Again, there can be little doubt that we have various magnetic inequalities, of which the periods are the same as those of the most prominent planetary configurations. May not, therefore, this magnetic inequality be connected with the intra-mercurial planet of the existence of which we are becoming sure, and is it not possible that a discussion of magnetic changes may aid us in settling this very interesting and important question?

St. Andrews, August 26 BALFOUR STEWART

Von Cotta's "Geologie der Gegenwart"

YOUR journal contains, in the number for August 8, a short notice of my newly-published "Geologie der Gegenwart," with a signal misrepresentation of the coloured frontispiece, beginning with the lines, "We can scarcely regard," to the end of the paragraph.

The illustration in question really is a representation of the fact that igneous rocks—both volcanic and plutonic—being originally products of the central parts of earth, form different species, according to their being rich in silica (acidic rocks) or poor in silica (basic rocks), and according to their consolidation at a considerable depth as *plutonic*, or nearer the surface as *volcanic* rocks. Becoming solid at a great depth, the *acidic* fluids have formed granites or porphyrites; nearer the surface, trachytes or trachytic lavas. The *basic* fluids, on the other hand, became syenites or greenstones at a great depth, and basalts or basaltic lavas nearer the surface.

All these various rocks by no means belong to particular geological periods, but *at all times* have either overflowed or penetrated other formations, and been accompanied by tuff formations.

The misapprehension contained in your notice is doubly painful to me, because I think I have been the first German geologist who decidedly adopted Lyell's view with regard to the utter independence of the nature of rocks from their geologic age: witness the first edition of my "Geologie der Gegenwart," published in 1866. BERNHARD V. COTTA

On the Wax of Pœciloptera

A SPECIES of Pœciloptera was this year rather common in the neighbourhood of this city, covering thickly the branches of *Cassia obtusifolia*, L., and more sparingly of *Cassia spectabilis*, D.C. I have not the means of identifying the species; I inclose, therefore, the wings of a specimen, so that some entomologist may give you the right name.[1] The females of Pœciloptera, as indeed of many other Fulgoridæ, are known to have the property of secreting a wax-like substance from between their abdominal rings, and especially from peculiar appendages of the last ring. This substance is, in the present species, of a beautiful white colour, glossy like silk, and formed of exceedingly thin threads, 1·500 to 1·700 of a millimetre thick, and generally less than a centimetre long. When taken off the living insect, the latter will be found to produce new threads in somewhat less than twenty-four hours. The threads are pure wax, lighter than water, insoluble in cold alcohol and ether, but dissolving a little in hot alcohol, and very easily in hot benzol. The fusing-point I found by repeated experiments to be *a little higher* than that of boiling water, though I could not determine it exactly, owing to the small quantity of wax I had collected (from 150 insects I obtained but six centigrammes of wax). In a heated silver spoon, or on platin-foil, the wax melted very easily, leaving no residue whatever. The molten wax was at first of a light yellow colour, which disappeared again after its getting cold.

The late Mr. D. Hanbury, in a paper on the insect-white-wax of China ("Science Papers," 62), quotes the statement of Capt. Hutton as to the properties of the wax of *Flata limbata*, an insect closely related to the Pœciloptera. It is said to "dissolve readily in water, while the attempt to melt it on the fire without water or oil proved altogether abortive, the wax merely burning and consuming away till it became converted into a hard and baked substance." This is certainly very singular, and it appears to me highly questionable whether Capt. Hutton's so-called *wax* was any wax at all.

I have not been able to find out what can be the benefit the insects derive from these copious secretions; but as they occur only in the females, there will probably be some connection with the egg-laying or hatching process. I observed no males, and could discover no eggs even in places where the females were thickly crowded on the branches. I should add that the insect is generally rather uncommon in our local fauna.

Spontaneous Combustion of Wasps' Nests

SOME time ago the house of General P. M. Arismendi (now Consul of Venezuela, in Port-of-Spain, Trinidad) in this city, had a rather narrow escape from being set on fire by the spontaneous combustion of a large wasps' nest (a species of *Polistes*) in a closet under a roof. The day was exceedingly hot; but this circumstance, I think, has a very slight connection (if any at all) with the outbreak of smoke from the nest. Roofs in this country are constructed of tiles supported by a thick layer of compact earth, which rests on the usual lath-work of dry canes (the stems of *Gynerium saccharoides*, or arborescent grass), both being substances that conduct heat very badly.

[1] An entomological correspondent informs us that the wing is that of *Pœciloptera phalænoides*, Linn., and agrees with Stoll's figure of the insect from Surinam.—ED.

The source of heat must therefore have been in the nest itself. In bees-hives the temperature rises sometimes as high as 38° C. (*teste*, Newport, as cited in Girdwoyn, "Anat. et Physiol. de l'Abeille," p. 23). We may be allowed to suppose that something similar happens occasionally also in wasps' nests. Such a heat might be caused by an alteration beginning in the wax, hydrocarbons being formed, which, on being absorbed by the paper-like, porous substance of the cell-walls, must get still more heated, so that a comparatively small access of oxygen would be sufficient to set the whole nest on fire.

I have been assured that the spontaneous combustion of wasps' nests is a well-known fact in the interior of Venezuela, and as I do not recollect having found it mentioned in books, it appeared to me worth while to inquire whether something similar has been observed in other parts of the world, and if so, whether my explanation will hold good in all cases.

Carácas, July 15 A. ERNST

Observations on a "Dust-Whirl"

WHILE making magnetic determinations at Kirksville, Mo., several "dust-whirls," or small whirlwinds, were observed, which, although not destructive in their effects, were unusually violent. The dust was carried by strong surface-winds, which rushed inward to the centre of the whirl, rising in a vast column 200 feet high.

One of these whirls crossed a pond of water, moving very slowly, and in a zigzag path. The water immediately became agitated, a *depression* was formed, which extended to the bottom of the pond (which was about five feet in depth). The top of the cup-shaped depression was about six feet in diameter, the bottom about four or five feet. There was no water drawn up from the pond, so far as could be observed, although a little of the rapidly whirling water at the edge of the depression was thrown outwards upon the surface of the pond.

Kirksville is situated in the northern part of the State of Missouri, and on the summit of the divide between the Mississippi and Missouri Rivers. During the present summer it has had the least rain in the State, and is yet parched by excessive drought. FRANCIS E. NIPHER

August 5

The Telephone

ON to the centre of a telephone vibrating disc, and perpendicular to its plane, a light needle ½ inch long was soldered, the disc held in a holder, mouth-piece, &c., the same as a telephone, and so arranged that the needle would vibrate in a small cylindrical ebonite cup, ¼ inch in diameter and ⅜ inch long, the top of the ebonite cup just free from touching the vibrating disc; a copper wire was let into the centre of the bottom of the cylinder, flush with the bottom; the cylinder was filled full with the finest dust of iron filings well shaken down.[1] A battery circuit was then completed with connecting wires, through the vibrating disc, iron filings, the copper wire let into the bottom of the cylinder, and through a pair of telephones in a distant room; after finding out by experiment the distance off the speaker ought to stand when speaking to this transmitter, and the proper degree of loudness he ought to give to his words, the voice came as clearly (and louder) as if a telephone had been used for a transmitter. If the speaker came too close or spoke too loudly the words were indistinct, and mixed up with a fizzing sound. In the experiment which was most successful the speaker was about 18 inches from the transmitter and spoke in an ordinary tone of voice. But this distance I found to vary with the thickness of the vibrating disc; a thin disc transmitted clearly only when the speaker was 3 feet off.

The ebonite cylinder was also filled with water (distilled) as an experiment, instead of iron filings. I thought that possibly the resistance of the circuit would be altered through the water, as the needle vibrated to and from the copper wire opposite to it; but no sounds were found to be transmitted. If the resistance of the circuit was altered when the disc vibrated in this experiment, it might tend to support the idea that alteration in the resistance of a circuit was not the only thing required to cause sound to be transmitted, but that "false contact" was necessary, such as would take place when the needle vibrated in the iron filings. G. R. R. SAVAGE

Roorkee, July 8

[1] The disc well tapped with the hand so as to loosen the filings round the needle.

The Electro-Magnet a Receiving Telephone

THE result I have arrived at whilst experimenting in this direction seems so interesting, and at the same time, I believe, novel, viz., *that a good receiving telephone can be made from electro-magnets alone without any vibrating diaphragm*, that I hope by prior publication, to prevent the possibility of a string of those patents which nowadays so greatly hamper true scientific invention.

In my earlier experiments I made an electro-magnet out of a piece of ⅜-inch iron gas pipe ⅜ inch long, filed flat on one side, and split sufficiently only to allow the wire (No. 24) to be wound on, which was done till it was full inside. The poles were therefore together about ⅜ inch square. This was fixed inside a small cigar box, under a ferrotype plate, covering a rectangular hole cut in the lid 2¼ inch by 1½ inch. With a Hughes' carbon-pencil-microphone tilted to an angle of 45° as a transmitter, a small musical box as a source of sound, in a distant part of the house, and one of Leclanché's cells in circuit, this box gave out tunes plainly heard by all sitting in the room.

Whilst experimenting with another similar magnet, I stood it loose, poles downwards, but still connected with the line wires on a flat tin gunpowder canister with the ends cut off, but still retaining the paper label on which the magnet lay; the tune of the musical box was given out loudly and resonant, but buzzing and jangling; also words spoken to the transmitter were heard, but confused together.

Now this was a very interesting result, which led to the next discovery; for, having a small ordinary electro-magnet with its armature in front (as used in electric bells), fixed to a piece of board, I was about to unship it to try experiments in various tin cans, &c., when it occurred to me to connect it as it was, to the line wires, placing only a slip of paper between the poles and armature to prevent actual contact. To my astonishment, on putting the ear close to the board at any part, the music of the box was heard clearly, every note from highest to lowest being distinctly given. Now here seemed to be a telephone without a vibrating diaphragm; but, to make more sure, the armature was unscrewed from its support and attached to the magnet only by an india-rubber band, with the slip of paper between it and the poles, so that it touched no other part of the apparatus. On listening to the supporting board, the sounds were heard as distinctly as before.

But even here forensic ingenuity might claim and attempt to prove that this ordinary armature was a vibrating diaphragm; therefore, an armature being itself nothing but an induced magnet, it was replaced by another electro-magnet, thus:—

Two ordinary electro-magnets (unscrewed from a couple of large electric bells) were fastened, by means of two little wooden saddles and a screw each, to a small piece of deal board about 4½ inches square and ⅝ inch thick, in such a way that the poles were all but touching. Their wires were then joined so that poles of opposite denominations faced each other, *i.e.*, north opposite south and *vice versâ*. This placed on an empty cigar-box and four Leclanché cells in circuit, gave out the tune of the musical box clearly and loudly in the room. When both poles were made to touch, the sound ceased; but with a thin piece of paper or stout tin-foil between them, without any intervening air space, the sound was heard. On gradually separating the magnets, the sounds grew fainter and fainter, till they became inaudible.

By putting the base-board close to the ear, whistling and singing to the microphone were very clearly and loudly heard, also the voice of the person speaking could be recognised; but words were hardly sufficiently defined to distinguish all that was said, though now and then parts were intelligible.

One of the electro-magnets was afterwards replaced by a small permanent steel horse-shoe magnet fastened to the board in a similar manner, the result was the same, but, I imagined, slightly louder, probably from there being less resistance.

By varying the strength of battery, size, or mode of mounting magnets, or adjustment of the microphone, I have no doubt that perfect definition can be obtained. The loudness and volume of the sound are ample; but before making further experiments, for which I have at present little time, I hasten to communicate the *fact* that *the electro-magnet, without any diaphragm whatever*, can be made a reproducer of sounds transmitted by a Hughes' microphone, and thus *a complete and practical telephone system produced without the possibility of infringing anybody's patent.*

I must add that the same arrangement is also a feeble transmitter, using a good Bell's telephone as a receiver, which is a very strange fact. I abstain at present from all theory on the subject. F. G. LLOYD

The Sea-Serpent Explained

On Monday, August 5, a number of geologists crossed in the Folkestone boat to Boulogne, to study the interesting formations of that neighbourhood, and, when about three or four miles from the French coast, one of these gentlemen suddenly exclaimed, "Look at that extraordinary object passing across the bow of the steamer, about a mile or a mile and a-half in advance of us!" On turning in this direction there was seen an immense serpent, apparently about a furlong in length, rushing furiously along at the rate of fifteen or twenty miles an hour; it was blackish in front and paler behind; its elongated body was fairly on the surface of the water, and it progressed with an undulating or quivering motion: *mirum erat spectaculum sane*.

Of course many suppositions were immediately started to account for this extraordinary phenomenon, but they quickly changed and settled into the fixed idea that the object before them could be nothing less than the great sea-serpent himself; for,—

> "Prone on the flood, extended long and large,
> Lay floating, many a rood, in bulk as huge
> As whom the fables name of monstrous size,
> Leviathan; which, God of all his works
> Created hugest, that swim the ocean stream."

The writer fortunately had with him one of Baker's best opera-glasses, and, after a few moments' use of this little instrument, the wonder was satisfactorily resolved. The first half of the monster was dark and glittering and the remainder of fainter hue, gradually fading towards the tail. The glass did not determine the matter until the extreme end was reached, and then it was seen to consist of a mass of birds in rapid motion; those that were strong on the wing were able to keep well up with the leaders, and so make the head appear thicker and darker by their numbers, whilst those that had not such power of flight were compelled to settle into places nearer and nearer the tail. Doubtless these birds were shags (*Pelicanus cristatus*) returning to their homes for the night from the distant waters in which they had been fishing, during the day; perchance it may be wrong to assert positively as to the variety of bird, but inasmuch as the writer has often seen shags on the Cornish coast in smaller numbers returning in single or double file to their roosting places, and since it is stated in works of natural history that they have been noticed occasionally flying in this peculiar manner to the number of a thousand or more, it does not appear an unwarranted liberty in supposing that they really were *Pelicani cristati*.

It is to be feared some of the geological gentlemen still doubt the interpretation of the lorgnette, preferring the fond deceit of a large and unknown serpent; but as in this case individual birds (scores of them) were distinctly seen flapping their wings, the writer has thought it his duty to report the circumstance to you that your readers who voyage across the seas may keep their opera-glasses in their pockets and verify for themselves, on the first opportunity, this interpretation of the great sea-serpent. JOSEPH DREW

4, Foxgrove Road, Beckenham, Kent

Parental Affection in Sparrows

I SAW a touching little incident showing the affection of sparrows for their young on the Kennington Oval cricket-ground last Thursday afternoon, a description of which you may, perhaps, think it worth while to record.

The afternoon was fine and the ground was surrounded by a dense ring of spectators, when a young pale-coloured sparrow, under the guidance of both its parents, was trying to acquire the use of its wings. A slight wind was blowing towards the spectators, and the poor little bird, in its weak attempt to fly, was, to the evident consternation of its parents, carried straight into the laps of the inner ring of spectators, one of whom caught it gently in his hand and held it.

When taken hold of the young bird gave two or three chirps or calls for help, and the old birds flew to within a few feet of the ring of spectators, and, alighting on the grass in front of them all, began to "beg" for the young bird in the most touching and beseeching manner. This they did by lowering their heads and making the peculiar flutter of the wings by which young birds beg for food from the old ones. This singularly touching appeal moved the hearts of many in the crowd, who called out—"Look! look at the old birds!"—"Don't hurt the young bird!"—"Give it back to them," &c. The anxiety and the boldness of the old birds and their humble beseeching for the young was so evident as to come home to the hearts of these somewhat rough spectators.

My own feeling certainly was that I could not have believed that a pair of sparrows could possibly have "begged" with such touching humility and tenderness for the safety of the young bird. Their manner clearly displayed their sense of their own want of power to help the object of their affection, they therefore prayed for mercy in their own way, and with so much feeling, as to excite the full sympathy of the crowd looking on, and to make them, for the time, forget the game of cricket they had come there to see. C. R.

Bristol, August 17

PHYSICS IN PHOTOGRAPHY

In taking a retrospective glance at the remarkable phenomena exhibited in photography, an endeavour will be made to explain them as far as possible by the light that may be thrown upon them by modern research, and at the same time to suggest extensions which probably may be given to this branch of science by further investigations. We may perhaps be open to rebuke from some for venturing to call photography a science; but surely as long as there are problems in it to be solved which require direct scientific solution, and which perhaps indirectly lead to the research in other directions, so long, at least, must it be something beyond a mere industrial pursuit. It is not the fashion to deny to electricity the honourable distinction of being a science, although it has become an industry in its application to telegraphy; why, therefore, it should be considered correct to consider the study of the chemical action of light upon compounds as something to be remitted to the intellect of those who are merely interested in it commercially, it is difficult to understand. It would surely be much better that men of science who employ photography in their laboratories and observatories, should endeavour to understand the science of attack with the weapon they are using, instead of regarding it as a simply mechanical agency, which is only worthy of the attention of, perhaps, a half-educated assistant. If our men of science who employ both were to be as ignorant of the principles of electricity as they too often are of those of photography, research would be very much restricted in its results; and it may, it is believed, be said with truth that a familiarity with even the first principles of photography would very much extend it. We may remark, by the way, that to instil a love of science into youth, an education in photography would seem to be of great value, as experiments can be made which have a real meaning to the experimenter, and which, by allowing an almost endless variation, offer an unlimited field for the exercise of the reasoning faculties. A study of photography, in short, must encourage the study of chemical and physical sciences, if a distinction may be made between the two.

Photography must undoubtedly be divided into two distinct branches: the direct production of the visible image by light itself, and the development of the invisible image by chemical means. The recognition of the former we owe to Wedgwood, and of the latter to Daguerre. The discovery of the former is much less remarkable than of the latter, since, without any particular research, a discoloration of a compound by light must have been noticed, whereas the development of an invisible image would have been a matter of theoretical reasoning, unless accident showed its feasibility. We know that the development of Daguerrean images was discovered accidentally by Daguerre, and we also know that the development of the image on paper was discovered accidentally by Reade. Without two such wonderful strokes of good fortune the growth of photography might have been retarded for years. The years which succeeded the discovery of the developable image were productive of research into many of the phenomena exhibited by the action of light on sensitive compounds, and, owing to the great intellects

who gave their attention to it, many important problems in photography were solved. Succeeding these years, however, were others in which little was done in the absolute science of the subject, though great progress was made in perfecting the processes which had been brought forward. Within the last few years a fresh start in research in all directions seems to have been made, and much that is valuable in elucidating the correct theories on which photography is based has been demonstrated, and it is to this to which attention will be drawn.

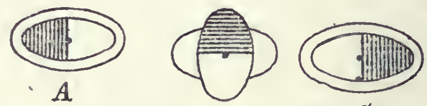
With the risk of being tedious, ground which has been well trodden must once again be briefly gone over, in order to estimate the progress which more recently has been made. Scheele, the Swedish chemist, as is well known, found that the blackening of silver chloride (which was the basis of Talbot's pictures) gave up chlorine on exposure to light, thus proving, as it were, that the blackening was due to the formation of a new chemical compound. As far as can be traced not much more was known regarding this compound; but it was a generally-received notion that it was a subchloride of silver; and up to the present time we find that such is the accepted opinion. In the second edition of Hunt's "Researches on Light," published in 1854, at p. 79, a remarkable experiment is noted. He says:—"The exposure (of silver chloride) in the water was, in another case, continued for several days, but no greater degree of darkening occurred; but a curious fact was noticed. It was found that during the night nearly all the chlorine which had been liberated during the day was recombined, and that the darkened powder became lighter" . . . . He then, after recounting other experiments, says (p. 123):—"From other experiments I am inclined to believe that the first action of the solar ray is to liberate one half of the combined chlorine, which is very readily, moisture being present, replaced by oxygen. By the continued action of the exciting cause the oxide is decomposed, and metallic silver in a fine state of division, is formed over the surface" (of the paper).

P. 125:—"The absorption of oxygen, or rather its combination, with the decomposing chloride is proved by another very easy experiment. Some pure chloride of silver was arranged in a bent tube closed at one end, and the other end immersed in a bottle of distilled water. In this state the chloride was exposed for many days to the action of sunshine, during which time it was frequently shaken for the purpose of exposing the whole of the powder and its influence. As the chloride darkened, the water rose in the tube, and it gave a precipitate of chloride of silver on the addition of the nitrate, thus appearing to prove the substitution of oxygen for chlorine under the agency of solar radiation. It was quite evident that some absorption of atmospheric air had taken place. This explanation will also serve for the iodide, bromide, and some other salts of this metal (silver)."

This last experiment has lain fallow for years, and it is only recently that it has had any meaning beyond that indicated in the quoted paragraph. It must be borne in mind, however, that the visible change in the chloride is here under consideration, and that the invisible effect of light was not mentioned.

With regard to the developable and invisible image, till within the last few years, it was a debatable point as to whether the action of light on a sensitive compound was really a chemical change, or simply a physical action; one school held that the sensitive compound was not altered in composition at all, but that in some mysterious manner the atoms of the molecules composing it were shifted, and possessed a new property which was denied to it in its original form. Diagrams were introduced to render this subtle change clear to the student, one of which is reproduced (Fig. 1).

In A we see two ovals slightly differing in size, each of which was intended to indicate one of the atoms composing a molecule of the sensitive salt. When the ovals coincided, the molecule was supposed to be in the ordinary state, but after light acted upon it for a certain time the ovals occupied the positions shown in B, and after a further action of light they occupied the positions shown at C, in which it again became incapable of proper development, and gave rise to what was known as *solarisation*, the part of the "*latent image*" formed by these solarised molecules refusing to *develop*. By solarisation was meant the phenomenon which occurred (more especially if silver films containing iodide were used), when any portion of the plate received a lengthened exposure to any very bright part of the lenticular image, such as to that of the sky. In solarisation we have have a term which is as unmeaning as is "polarisation" in some of its applications, but since it has passed into the technical language of photography, we are bound to employ it. By the term latent image was meant the invisible (and usually) developable image impressed upon a sensitive film, and it will be used, where convenient, with the reservation once for all, that its applicability is not admitted any more than is the term "developer," as applied to a solution which may cause the deposition of metallic silver from a solution of silver nitrate; since such a solution is effective whether applied to an exposed sensitive film or not. The advance of photography has literally been impeded from the neglect of using accurate language. As regards this peculiar condition which the molecule was supposed to have attained after its impact with light, there seems to be no ground for its adoption. The idea seemingly arose from a supposed necessity which existed for a difference in condition between the visible and the



A B C

Fig. 1.

merely developable image. By a strictly logical inference there need be no difference between the two beyond this that there should be a difference in the number of molecules absolutely altered, and in no other respect. Perhaps the most telling experiment giving *direct* evidence of the similarity of the two images was that made by Poitevin, in which he proved the dissociation of iodine from silver iodide, by placing metallic silver in contact with the film. After exposure to light, on separating the two, he found that the latter had absorbed iodine, as proved by treating it with mercury vapour. The *circumstantial* evidence of the truth of the chemical theory of the invisible image, however, is so strong, that on that alone we are bound to accept it, at the same time we are not prepared to say that there are not other physical forces which must play a part in its development; in fact, it must be so. We may say, then, that at its *first formation* the developable photographic image is formed by the reduction of the sensitive compound to one of a less complex nature. Thus, silver chloride (argentic chloride) is reduced to silver sub-chloride (argentous chloride) with the liberation of chlorine; and silver bromide to silver sub-bromide with the liberation of bromine; and so on.

We must now allude to the development of the photographic image. We may divide the methods of development of the image on silver compounds into three: (1) The condensation of mercury; (2) the deposit of metallic silver from a soluble salt of silver by means of a reducing agent such as ferrous sulphate; and (3) the reduction of the sensitive salt of silver itself to form the image.

The first method is the earliest, dating from the discovery of the Daguerrotype process, and till within very recent times the reason of its efficacy has been a subject of controversy. Quincké has lately thrown a light upon

it in one of his memoirs, and his explanation seems to account for it in a most perfect and philosophical manner.

In the Daguerrotype process, it will be remembered, a silvered plate is subjected to the vapour of iodine (or of iodine and bromine), and thus receives a fine layer of a compound which is sensitive to light. When a plate so prepared is exposed to a lenticular image in the camera, the light causes the iodide (or bromoiodide) of silver to throw off iodine (or this together with bromine), which is immediately seized by the silver beneath, and thus forms a deeper layer of the sensitive salt. The depth, almost immeasurable though it be, depends on the intensity of, and length of exposure to, the light. (That this is the case has been proved by the fact that, if the sensitive layer be removed by a suitable solvent, the surface beneath is shown by reflected light to be etched to a greater or less degree.) The invisible image thus formed is exposed to mercury vapour, and the dew condenses on it proportionately to the depth of the layer. Quincké, in his memoir "On the Edge Angle and Spread of Liquids on Solid Bodies,"[1] shows that the edge angle of a drop of liquid on a solid body varies from zero to a constant quantity, according to the thickness of any fine layer of impurity which may be on the latter. When this layer attains a certain value then the edge angle of the drop will remain constant. The thickness, or rather the thinness, of the layer may be appreciated when it is stated that it bears a relation to what is called "the radius of the sphere of sensible action of molecular forces," and is usually greater than ·00005 millimetre. In this case the sensitive plate is the solid body and the invisible image forms different thicknesses of impurity. By this difference in the edge angles of the mercury dew, condensed on different portions of the latent image, the light is reflected in different ways, which gives rise to the visible image.

This explanation entirely does away with the necessity, which previously seemed to exist, of the silver iodide (or bromo-iodide) being reduced to the metallic state, in order to cause condensation, or—perhaps it might be said—to cause the formation of an amalgam of mercury and silver.

The next method of development speaks for itself; the metallic silver is deposited in fine granules and is attracted by the salt which has been altered by the influence of light. Perhaps further investigation will show that development is dependent on what is known as the Brownian movement, or the rapid movement of small suspended particles in a liquid. If this movement be dependent on the electrical condition of the neighbouring body, as has lately been supposed; and if, as Dewar has shown, the condition of an exposed sensitive salt is electrical, then the deposition of the metallic particles of silver on the image is accounted for in a satisfactory manner.

The last mode of development is principally employed with silver bromide, and is known as the alkaline method. When a film of collodion or gelatine holds a sensitive salt on a plate, the portions exposed to light are reduced to the metallic state by the application of an oxygen absorbent such as alkaline pyrogallic acid. Since the image is invisible, it must be remembered that but a few molecules of the sensitive salt are reduced by the action of light to the less complex and developable form, we therefore must look for some further action between the developer and the rest of the unaltered compound. It has lately been proved that silver bromide or silver chloride cannot exist in *close* contact with metallic silver. It invariably forms the developable salt. Thus if we take a glass plate, silvered by any of the well-known processes, and expose it to the fumes of bromine or to hypobromous anhydride, it will be found that it is impossible to secure a film of argentic bromide until the last trace of silver has been attacked, after which the true colour of argentous bromide gradually gives way to the well-known colour of argentic bromide. We may try the experiment with bromine water and the same holds good. The action of chlorine on silver is the same as of bromine, but the action of iodine seems to be different, the fully saturated compound, argentic iodide, being formed at first. In other words, this compound is the more stable than argentous iodide.

Now the alkaline developer, when mixed with a soluble bromide of an alkali, has the property of much more readily attacking the argentous than the argentic bromide, presumably because the soluble bromide used in development combines with the former, giving rise to an apparently difficultly reducible compound, whilst it refuses to combine with the argentous salt. It is thus easy to see, if this property of the developing solution be connected with what was stated in the preceding paragraphs, how development takes place. The developer is applied to the exposed film, and the minute quantity of argentous compound is reduced to the metallic state, and at once this particle of silver which is in close contact with the unaltered compound combines with it and forms new argentous bromide. This is ready for attack by the developer, and thus the action spreads till the whole thickness of the sensitive salt is reduced to the metallic state where the greatest exposure has taken place. An interesting result[1] of this action is afforded by the fact that, if a film of unexposed argentic bromide be superposed over one that has been exposed, the image impressed on the latter can be developed in the former so long as close contact is secured. It has been said that this action is due to the solubility of the silver-bromide used in the alkaline development; and, to some extent, this is true; but it is evident that this cannot be explanatory of the whole phenomenon, since the same effect is produced by using, with the pyrogallic acid, potash as the alkali in which the silver-bromide is absolutely insoluble. We have been thus particular in showing the cause of this alkaline development, as it explains some phenomena to which attention will subsequently be called, and which otherwise would be inexplicable, except by reversing usually-accepted physical laws.

MILITARY BALLOONING

THE matter of ballooning for military purposes appears to be once more attracting attention in this country. In France they have now a properly organised service under the command of a colonel of the National Engineers, who considers all novelties and proposals as they arise, and who sees, moreover, that the State has always a body of skilled aëronauts at its disposal. At the end of the Paris siege the Postal department, it may be remembered, possessed a large number of balloons, and these being handed over to the French war minister, constituted the *matériel* necessary in the formation of a military balloon service. Col. Laussedat, whose name as an energetic officer of the French Topographical Department, is well known, was placed in command, and he at once secured the services of one of the Messrs. Goddard to put the whole of the apparatus in a fit condition for service. Since that day ballooning in France has been considered as much a duty of the Engineers of the army as telegraphing and surveying, and classes both for officers and men are held for instruction. Lately, by the resignation of Col. Laussedat, the French balloon service has lost its chief support; but his place has just been supplied by Gen. Farr, who will, no doubt, take measures to maintain the high efficiency which has been attained by his predecessor.

In France, as in this country, the balloon is chiefly

regarded by military men as an important means of reconnoitring. The Paris photographer and aëronaut, Nadar, was successful on several occasions in securing photographic records from balloons, but he never published his *modus operandi;* and the problem of balloon photography is one which still excites a good deal of attention. Mr. Walter Woodbury, the well-known inventor of Woodburytype—the only practical photo-engraving process we know—submitted, during the last war, to the Russian government, a very ingenious method of securing pictures at an altitude. By his plan no one ascends with the balloon at all, and therefore the latter may be of very limited dimensions. It is captive, and twisted into the tethering rope are insulated wires in connection with a camera. The camera is weighted and hung upon a pivot so as to be always horizontal, and a fan attached to the balloon prevents the same from gyrating. It is easy to understand how a lens may be capped and uncapped from below with the aid of an electric current, and the photographs are secured—for a series may be taken at one ascent—upon a length of sensitive tissue which is unrolled for use through the medium of clockwork. The sensitive tissue and roller arrangement is that of M. Warnerke, which is known to all dry plate workers, and which permits of securing pictures without glass. Mr. Woodbury's invention has, so far, been tested only in respect to its photographic properties, but in cases where an aëronaut would run too much risk, or where a large supply of gas is not available, the apparatus would be well worthy of trial.

It is the difficulty of securing a sufficiency of gas for inflation that at present stands in the way of employing balloons in the field. The French balloons are all large ones, for they were constructed most of them for postal service during the siege, and, besides the mails and aëronaut, sometimes carried three passengers. With the exception of half-a-dozen, all the balloons which left Paris had a uniform capacity of 2,000 cubic metres, while one, in which M. de Fonvielle and three other persons travelled from Paris to Louvain, measured 3,000 metres. Such bulky balloons as these are unsuited for the field, where the problem is to send a single observer aloft with the minimum amount of time and trouble. The smallest balloon and the lightest gas for the purpose are what the soldier seems to require, and it is towards these two points that attention has lately been directed by Capt. Templar and the other officers who are just now occupied in the study of aërial navigation in this country. Naturally enough, hydrogen holds out the most promising features as a lifting medium, and it is with this gas that experiments are once more to be made. As our readers remember, the weight of hydrogen is calculated to be 2·14 grains per 100 cubic inches, while air on the other hand weighs 31 grains; and, as the lifting power is represented by the difference between these numbers, it stands to reason that theoretically, a balloon, if filled with hydrogen, need be of but comparatively very small dimensions. Unfortunately, in a practical affair like ballooning, a lot of accidental matters require to be taken into consideration, and two of these are the facts that it is difficult to secure pure hydrogen, and more difficult still to keep it in the balloon envelope when secured. Capt. Templar is sanguine that a 10,000 cubic feet balloon is quite capable of lifting an observer high enough for reconnoitring purposes, if filled with hydrogen, and well-nigh proved his case the other day when he overcame gravity, if he did not rise, with the aid of a light coal-gas with which this small balloon was filled. The coal-gas, specially manufactured for his balloon, had a lifting-power of 50 lb. per 1,000 feet, so that a total of 500 lb. was here at his disposal. As we have said, this was insufficient for an ascent, for, besides the weight of the aëronaut, there are, it must be remembered, envelope, car, tackle, cable, and ballast to be taken into consideration. Instead of 500 lb., hydrogen of the same volume would have supplied a lifting-power of 700 lb., and this of course would have been ample, and to spare, for an ascent.

To make this hydrogen recourse will be had, as in previous experiments undertaken by our military authorities, to the decomposition of water in the form of steam. The latter is to be passed through tubes filled with iron filings or turnings, and these, in becoming oxidised, set free the hydrogen. Unfortunately the hydrogen obtained in this way is impregnated with moisture, and unless submitted to the action of some desiccating agent like quicklime, for instance, is of little good for ballooning. The hydrogen it is proposed to obtain in the field, at any rate, in this fashion, and it remains to be proved whether Capt. Templar and his colleagues can secure it sufficiently pure and in proper quantity under these practical conditions. Although hydrogen is given off fast enough at the outset, previous experimenters have found the supply to fall off rapidly, for as soon as the surface of the particles becomes oxidised the decomposition of the steam ceases.

But perhaps the most interesting feature of the present ballooning experiment will be the trial of compressed gas. As our readers know very well, compressed gases are now a commercial article in this country, and you may purchase cylinders of oxygen or hydrogen at twenty atmospheres pressure. As our Royal Engineers carry about with them in the field such unwieldy things as pontoons, they can hardly grumble at a waggon load of hydrogen tubes, and with these it is suggested to fill a balloon just wherever a reconnaissance is to be made. On nearing the enemy the first convenient spot will be chosen for the manufacture of the hydrogen, and this will then be compressed, with the assistance of suitable apparatus, into the tubes, to be drawn off again when the ascent is to be made. In this way there is always to be gas at hand not only to fill the balloon but to keep up a constant supply for a limited period, since hydrogen, under the most favourable circumstances, rapidly exudes from a balloon envelope.

A military balloon, it appears to be decided, must be a captive one, and opportunity would of course be taken to place the observer in electrical communication with the earth through the medium of insulated wires twisted round the rope in the same way as in Mr. Woodbury's photo-aërial apparatus above described.

H. BADEN PRITCHARD

HYPNOTISM

THE phenomena of "hypnotism," "mesmerism," or "electro-biology," have of late years excited so much popular interest—not to say popular superstition—that their investigation by a competent man of science will appeal to the sympathies of a wider public than the purely scientific. My object, therefore, in writing the present article is to give a brief review of a monograph on this subject, which has just been published by the well-known physiologist, W. Preyer of Jena.[1]

In order to eliminate all possible effects of the imagination, Preyer performed his experiments only upon animals, and he begins his paper with an historical sketch of previous investigations of a similarly restricted nature. First we have the "Experimentum mirabile" of the Jesuit Athanasius Kircher, published by him in the year 1646.[2] This consists in taking a common fowl, binding its feet together, and placing it on a floor. As soon as it has ceased to struggle a straight line of chalk is drawn from the point of its bill along the floor. If the legs are now

[1] Die Kataplexie und der thierische Hypnotismus. (Gustave Fischer, Jena, 1878.)

[2] In a postscript Preyer states that he has found this experiment to have been published ten years earlier, by Daniel Schwenter, and the quotation which he makes from Schwenter's book goes to prove that Kircher probably derived his knowledge of the experiment from that source.

untied the fowl makes no endeavour to escape, but remains as it were transfixed, and refuses to move even when urged to do so. Preyer observes in passing that the chalk line constitutes no essential part of the conditions, inasmuch as a fowl may be equally well thrown into a state of hypnotism by simply holding the animal for a short time upon the ground so as forcibly to prevent struggling.

After Kircher no one seems to have investigated the phenomena of hypnotism, or, as Preyer calls it, kataplexy, till the years 1872-73, when some articles on the subject were published by Czermak. The most striking of his experiments were those which he conducted on invertebrated animals—crayfish, for instance, being made to lie on their backs motionless, or even to stand upright upon their heads. Czermak endeavoured to account for the facts which he described by supposing that in some way or other the act of fixing the eyes upon a certain object, or of gazing into space, caused the animals to become sleepy and stupefied.[1] So vague an explanation could scarcely in any case be entitled to rank as a physiological hypothesis, and Preyer showed, in 1873, that the act of gazing had nothing to do with inducing the state of kataplexy, inasmuch as animals fell into exactly the same state when their optic nerves were divided, or their eyes covered with a hood—provided that their bodies were at the same time held in some unnatural position. Preyer therefore propounded a theory of his own, which, as first published, was that the state of fear into which the animal is thrown by being held in some unusual attitude serves to inhibit the power of volition and so of spontaneity—the animal, therefore, when released remaining statue-like in the position in which it was placed. In order to sustain this theory Preyer pointed to other cases in which fear serves to inhibit spontaneity—as, for instance, the motionless horror which some animals exhibit in the presence of great danger, the fascination of birds by snakes, &c. The theory as thus stated was very justly criticised by Heubel, who, in 1876, published a paper detailing his own researches on the subject, and seeking to identify the state of hypnotism with that of ordinary sleep. The effect of this criticism was to make Preyer state his theory with greater clearness, and as we now have it (1878), it seems to be as follows. Any "sudden, strong, unexpected, and unusual stimulation of centripetal nerves" produces an emotion of fear, which in turn produces some inhibitory effect on the will, and eventually a state of stupor. It may, I think, still be questioned whether this theory is of very much value, for even granting that "deathly terror" is always present—which it certainly need not be when the subject of the experiment is a human being—we are not acquainted with any other facts which would lead us to connect the subsequent state of motionless stupor with the preceding state of active fear.[2] But, passing on to the facts, we soon find that an important exception must be taken to the above statement as to the conditions under which hypnotism occurs, for various experiments proved that "sudden, strong, unexpected, and unusual stimulation" of any of those "centripetal nerves" which minister to the *special senses*, so far from inducing a state of hypnotism, instantly aroused an animal which had been previously thrown into that state. So that, in point of fact, as we are afterwards told, we may more correctly state the conditions which produce kataplexy in animals, by substituting for the words "centripetal nerves" in the above-quoted proposition, the words "nerves of tactile sensation." But here I may observe that, so far as the experiments go, there is nothing to prove that special stimulation of even the cutaneous nerves is necessary (indeed thermal and chemical stimulation of the skin was specially tried and produced no results); and therefore, it seems to me, the possibility is not excluded that the special stimulus in question may really have reference only to the "muscular sense." At any rate, all these experiments go to prove that kataplexy can only be produced in animals, either by suspending them in the air, or by forcibly holding them in some unusual position. Most animals recover their normal state after a few minutes, but frogs when suspended in the air will continue kataplectic until they die. Horses become kataplectic while they are being swung from wharves to ships, as shown by the fact that they remain passive so long as they are suspended in the air, but again begin to struggle so soon as their feet touch the deck. Preyer has succeeded in rendering kataplectic various species of toads, newts, frogs, ducks, poultry, pea-fowl, partridge, sparrows, mice, guinea-pigs, rabbits, &c.; but has uniformly failed in the case of many other animals. On the whole he concludes that while among sundry species of reptiles,[1] batrachians, birds, rodents, and ruminants, the phenomena of kataplexy may be more or less easily produced, such is not the case with fish and the more intelligent mammals. Nevertheless in another part of his memoir he attributes to a state of partial kataplexy the period of motionless delay which is observable in children after they unexpectedly fall and before they begin to cry. He also states, on the authority of Dr. Genzmer, that a squalling child (not a young baby) may often be quieted by laying it upon its stomach, or by gently pressing its face with the hand—care being taken in neither case to interfere with the breathing.

Our author further maintains that the so-called "shamming-dead" of certain species of *Articulata* when in the presence of danger is probably to be attributed to kataplexy. But here, I think, it is difficult to agree with him. That the action in question is not a properly so-called *intelligent* one, no competent person at the present day is likely to dispute; but for my own part I cannot see any evidence to show that it is not of the nature of an instinctive action which has been developed in the way to which Preyer alludes. It being for the benefit of some animals that they should remain motionless, and thus be comparatively inconspicuous in the presence of danger, those individuals which endeavoured to escape would be destroyed, while those which ceased to move would survive. Natural selection would therefore soon fix the artifice of "shamming-dead" as an inherited instinct. To this view Preyer objects that, if we accept it, the *origin* of the instinct is difficult to explain; while on the supposition of the action not being instinctive, but purely kataplectic, there is no difficulty to surmount. But to this it may be answered that there is no more difficulty in explaining the origin of the instinct to remain passive in the presence of danger than there is in explaining the

[1] When we fix our eyes upon a certain object and then alter their adjustment for some more distant point, so that the eyes endeavour, as it were, to look through the object, there is no doubt that after a time a somewhat sleepy feeling may be produced. Some persons, I find, can perform this action more easily than others, and it does not seem to consist altogether in maladjustment. At least I have observed that when the action is performed by persons who can do it well the pupils dilate prodigiously, and this even when the eyes are fixed upon a bright light such as the naked flame of a moderator lamp. As the action is completely under the control of the will, one is thus able to observe the curious spectacle of the inhibition by the will of a reflex which under all other circumstances is beyond the control of the will—the pupils dilating or contracting instantly at word of command, and quite irrespective of the stimulus supplied by light.

[2] Indeed a very remarkable experiment which is detailed further on would seem to show that even in the case of animals the state of fear need have nothing to do with inaugurating the state of kataplexy. The experiment in question consisted in suddenly decapitating a fowl, and while the reflex convulsions were still in progress, holding the mutilated body firmly on its back. The convulsions forthwith ceased, and the headless animal became for a time kataplectic. Unless, therefore, we suppose that the spinal cord is capable of suffering fear, and that it is more alarmed by being held firmly down than by being severed from the brain, we must conclude that a state of fear is no essential antecedent to that of hypnotism.

[1] Preyer does not appear to have himself experimented on any species of reptile, but in another part of his monograph refers in this connection to a very old authority, viz., Moses, whose power of causing serpents to appear like rods he supposes to have been probably due to the sagacious Israelite having known something about the phenomena of kataplexy. But considering the number, variety, and general quality of the experiments which Moses is said to have performed, it would surely be desirable to repeat the one in question before accepting the result as a fact of modern physiology.

origin of any other instinct—that of running away from danger included. Moreover, one of the animals to which Preyer refers, viz., the *Armadillo vulgaris*, not only remains motionless when alarmed, but rolls itself up into a ball—an action which certainly cannot be explained on the hypothesis of kataplexy. The most, therefore, that can be said for this hypothesis is, that possibly in its first initiation the instinct may have been assisted by the occurrence of kataplexy.

The time during which the kataplectic stupor lasts varies in different species of animals, and also in different individuals of the same species. The maximum duration observed in the case of rabbits was twelve minutes; but fowls and guinea-pigs continue stupefied for a somewhat longer time. By watching carefully for the first indications of recovery, and by preventing the voluntary movements in which these indications consist, animals may be kept in a state of kataplexy for an indefinite time. Warm-blooded animals do not suffer from such prolonged experiments; but the latter are fatal to frogs. In mammals the most characteristic features of the kataplectic state, besides that of unconscious stupor, are violent tremblings of the extremities, blinking of the eyes, movements of the jaw and pupils, irregularity of the pulse and breathing, pallor of ears in rabbits, occurrence of defæcation and micturition. On recovery the abnormal state passes off suddenly, leaving the animal bright and brisk as before, and thus, as in so many other respects, the state of kataplexy differs from that of ordinary sleep.

One other point of interest must be noted. Preyer finds that it is impossible to produce the state of kataplexy in any animal that is "newly-born." In the case of guinea-pigs susceptibility to be thrown into this state only begins to show itself during the first week after birth, and then gradually increases through two or three weeks. This curious fact is explained by the hypothesis that the volitional centres—or the centres which are supposed to be affected by kataplexy—require some time after birth to be brought into functional relation with the lower centres.

On the whole, then, it will be seen the facts relating to the hypnotism of animals are much more definite than the theories by which it is sought to explain them; and although we may be prepared to agree with Preyer that these facts in some way depend on certain unusual stimuli acting in some peculiar manner on some inhibitory centre or centres, we must feel that this statement of the case brings us only to the threshold of an explanation. GEORGE J. ROMANES

HYDROGEOLOGICAL SURVEY OF ENGLAND

FLOODS, or water in excess above ground, form one of two extreme conditions, of which the other is drought, or water in defect below as well as above ground. The requirements of water-supply induce the necessity for storage. Out of these three simple facts arise several intricate public questions. Thus it is evident that, if floods are to be controlled, some one must have authority over the rivers, and inasmuch as floods are intensified by land drainage, that authority must extend over the whole of the watershed area if it is to execute measures of a sufficiently comprehensive character to be effective. As works cannot be constructed without money, it must also have rating powers over the whole river basin for the purpose of raising the necessary funds to cover the cost of such remedial works. But inasmuch as the flooded lands bear a small proportion to the contributary area, that is, to the rest of the watershed basin, the consequent preponderance of influence and capital is largely in favour of the unflooded portions. Therefore, if the case of floods rested for its remedy solely upon the loss sustained by riparian owners, it is doubtful whether the British public would ever be brought to see the desirability of moving in the matter. Drought, however, is felt by an increasing population, whose interest in having a proper water-supply is as deep as can be desired. The public looks to the engineer to provide proper storage, who is thus called upon to unravel at least two of the knots that surround the subject of rivers considered in relation to the storage of water. The first of these is of a purely physical kind, and is simply this: that whereas water for the purposes of water-supply is required at high levels, the pure rain which falls upon the declivities of the watershed area at once proceeds to find the lowest level or the deepest ruck in the valley, down which it courses, along the natural main drain of the basin, and below the level of all possible habitations, to the sea. Therefore, before it can be used, it must be lifted out of this ruck. Here steps in the second difficulty. Some one has a vested right in every yard of this water, and a real or supposed interest in obstructing every attempt to divert any portion of it. Waterworks having rivers for their sources have for these reasons proved too expensive for scattered populations in the past. Nevertheless, when fish was a necessary article of diet, the money and influence were forthcoming to cause the construction of a series of very noble ponds, and subsequently when the manufacture of iron flourished in the south of England, many more were added for the purposes of water power; while in some cases water was diverted from the main channel and carried in an open conduit, as in a mill race, with the same object in view. In the case of canals, much of the best and purest spring water the country contains has been degraded from its higher uses to the purpose of a common carrier, but now that the requirements of the population have changed, and it is no longer essential either for the one purpose or the other, but is wanted for drinking, it should be the aim of the engineer to do for water supply what has been done for water power, but on a more comprehensive and extended scale, viz., to keep the water as high as possible by diverting as much as he can take from the upper tributaries, and causing it to contour as far as possible along the ridges with a view of commanding the largest extent of country by gravitation, and to compensate the main channel by a series of storage ponds. Numerous instances may be found in the lower greensand districts in Surrey, formerly a seat of the iron trade.

As a whole, the country is more largely dependent upon subterranean sources, or upon wells, for its water supplies than it is upon rivers. Inasmuch as every well that is sunk increases by a small amount the storage capacity of the stratum, the tendency is in the direction of a gradual lowering of the water-line. The resources of the subterranean water systems cannot be taxed indefinitely. Under London an elliptical vortex has been pumped out whose dimensions below sea-level are twenty miles long, eight miles across, and 130 feet deep, the total amount of depression at the apex being about 150 feet. Yet we have very recent instances of destructive local floods in the Metropolitan area immediately above this great centre of exhaustion. These two considerations point to the multiplication of wells, coupled with a proper system of replenishment from flood waters, as a means of utilising these natural reservoirs. The restoration of the original levels under London would restore to upwards of one hundred square miles of country their lost property as Artesian areas of overflow, the value of which is such as to confer upon the surface its full value as building land.

Thus, as storage above ground is expensive, and generally in supposed conflict with the interests of rivers, few of the numerous natural sites for reservoirs in England have been utilised, except in some places in the southern counties, where they were dammed up for fish ponds and

water power; whereas storage below ground, excepting tanks, remains for the engineer of the future.

Since, then, the agricultural interest is an irresponsible flood producer, and makes no counter provision for the storage of the water prematurely taken out of the soil; and since existing Conservancy Boards have not the necessary powers to deal with floods; and since the claims of water supply are paramount, and, from being strongest in periods of drought, can only be met by provision from flood waters; and since again many of the subterranean water-systems are being steadily exhausted, it becomes evident that no existing authority has the powers necessary for the successful treatment of the various questions so interwoven.

Whatever shape or shapes this governing body may ultimately take, all authorities who have expressed their views upon these questions are agreed that a preliminary survey of the natural sources of supply is necessary. The collection of these essential premises to successful legislation and to successful engineering works lies within the special province of hydrogeology, which takes up the history of rain-water from the time that it touches the soil. The tangible product of the survey is a map, which shows at a glance the necessities and the capabilities of each river basin. By the execution of such a map and the mere exhibition of the facts, a great stimulus is given to engineering enterprise, and by the establishment of such a survey, as a forerunner to legislation encouraging the construction of all necessary works, and the consequent removal of the feeling of want of scope that has stood in the way of the engineer hitherto, Government will have earned the thanks of the engineering profession and of the nation at large. JOSEPH LUCAS

THE INTRA-MERCURIAL PLANET

WE publish the following three communications in reference to the observations and calculations of Prof. Watson on the intra-Mercurial planet, about the existence of which there now seems little doubt. It will be seen from the third communication that Prof. Watson has been led to slightly alter the place of the planet from that given in the foot-note to Mr. Lockyer's article last week.

Prof. Watson, it will be remarked, refers to a second object, which he considers probably new. The position of the nearest conspicuous star ζ Cancri, at the time of his observation, was in R.A. 8h. 5m. 14s.·4, and declination 18° 0′·9.

The following letter to Mr. Lockyer we referred to in the foot-note (p. 462) last week:—

"*University of Michigan, Observatory, Ann Arbor,*
"*August* 14, 1878

"Since my return I have placed the paper circles on a graduated circle, and have read off the marks made during the observations at Separation. The resulting place of Vulcan differs slightly from that which I inferred from mere estimation at the time of the observations.

"The place which I have now derived I consider to be trustworthy within 5′ of arc. It is as follows:—

Washington Mean Time.		R.A.	Dec.
1878, July 29 ...	5h. 16m. ...	8h. 26m. 54s.	+ 18° 16′.

"You are already familiar with the method which I adopted. If I were to do the work over again I would use the same method. It does not give the place so accurately as it would have been given by graduated circles and verniers, but it does away entirely with the uncertainty which might be attributed to an erroneous circle reading at the time. My circles are like the chronographic record of a star transit. They give the pointings for the planet and the sun, and the readings can now be made at will.

"You will be pleased to hear that the planet was seen a few minutes afterwards by Mr. Lewis Swift, who observed in the neighbourhood of Denver. Mr. Swift is known to astronomers by his discovery of comets. I do not know whether he obtained anything more than an estimate of the position; but the place in which it is reported that he saw the planet agrees with my observation. This corroboration is peculiarly fortunate, considering the negative results of other observers.

"JAMES C. WATSON."

The following has been forwarded to us for publication by the Astronomer-Royal:—

"*Keswick, September* 2, 1878

"I have received from Prof. James C. Watson the following communication in reference to the suspected intra-Mercurial planet:—

"'*University of Michigan, Observatory, Ann Arbor*
"'*August* 14, 1878

"'During the recent total eclipse of the sun, I devoted myself to a search for an intra-Mercurial planet. In order to expedite the record of position, I placed disks of cardboard on the circles of the equatoreal, and marked the pointings by means of a sharp pencil and a pointer. All danger of error from wrong circle-readings is in this way avoided.

"'In the course of the search, I came across a ruddy star of the 4½ magnitude, which had a perceptible disk, the magnifying power being only 45, and which was in a position where there is no known star. It was very much brighter than θ Cancri, which was seen a little further to the west. Its position was referred, by means of the circles, to the sun, and was as follows:—

Washington Mean Time.	Apparent α.	Apparent δ.
1878, July 29 5h. 16m.	8h. 26m. 54s.	+ 18° 16′

"'There was no appearance of elongation such as might be expected if it were a comet, and hence I feel warranted in believing it to be an intra-Mercurial planet. The details of the observations I will send you hereafter.'

"Prof. Watson's statement appears to render it very highly probable that the object seen is really an intra-Mercurial planet. I remark, however, that the reason for excluding the supposition of its possible cometary character does not seem quite conclusive, as, when the tail of a comet and the small appendages of its head are invisible, the nucleus is usually circular.

"G. B. AIRY"

The following letter to Mr. Lockyer, just received, contains Prof. Watson's latest statement on the subject:—

"*University of Michigan, Observatory, Ann Arbor,*
"*August* 22, 1878

"On account of a wrong value of the correction to be applied to Prof. Newcomb's chronometer, the place of the new star which I communicated to you last week was erroneous. Please substitute, in place of the numbers then given, the following:—

Planet − ☉
$\Delta\alpha$ $\Delta\delta$
− 8m. 21s. − 0° 22′

Washington Mean Time.	Planet's Apparent. α	δ
1878, July 29 5h. 16m. 37s.	8h. 27m. 35s.	+ 18° 16′.

"The more I consider the case the more improbable it seems to me that the second star which I observed and thought might be ζ Cancri, was that known star. I was not certain in this case whether the wind had disturbed the telescope or not. As it had not done so in the case of any other of six pointings which I recorded, it seems

almost certain that the second was also a new star. The position comes out

$\alpha = \odot - 27\text{m. } 18\text{s.} \qquad \delta = \odot - 35'$

And

Washington Mean Time.		Apparent. α	δ
1878, July 29	5h. 17m. 46s.	8h. 8m. 38s.	+ 18° 3'.

"JAMES C. WATSON"

Our Paris Correspondent writes that Admiral Mouchez has received a letter from Prof. Watson. M. Gayot has completed his calculations and finds that Prof. Watson's observations are in accordance with Dr. Lescarbault's discovery, so long denied by M. Leverrier's opponents.

GEOGRAPHICAL NOTES

THE Geographical Society of Paris took possession, on the 2nd instant, of their new hotel in the Boulevard St. Germain, No. 134. The ceremony took place at three o'clock, under the presidency of Admiral La Roncière Le Nourry, who delivered an address explaining that it was not an international congress, but merely a national meeting of the several French societies, to congratulate their eldest sister on the success which had crowned its efforts. M. Bardoux, the Minister for Public Instruction, who was seated at the right hand of the president, handed the papers of Officer of the University to the architect of the Society. He read a letter from M. de Ferri, the French consul at Zanzibar, intimating that excellent news had arrived from Abbé Debaize, the French explorer, now proceeding towards Tanganyika. The delegates of various French geographical societies afterwards gave addresses summarising the progress which has been made in the work which each is carrying on.

A MAP of France, for which a vote on account of 100,000 francs has been given by the Chambers, is being prepared by the parochial authorities on the scale of 1 to 100,000. It will be hydrographic, not orographic, levels being shown only by curves. Some of it will be issued by the beginning of next year, and two departments figure as specimens in the Exhibition. The road surveyors are to make any alterations from time to time so as to prevent its becoming obsolete. Names, railways, roads, and boundaries will be coloured black; water, blue; woods, green; and footpaths, red.

AN important and interesting discovery has just been made by Dr. A. Kirchhoff in the Library of the Halle University. It consists of a copy of a part of the original diary kept by Capt. Cook during his journey in the year 1772, beginning on July 13, 1772, and ending January 11, 1773. The volume was originally presented to the University by one of Cook's travelling companions, John Reinhold Forster, who died at Halle. Dr. Kirchhoff has communicated the contents of the volume to the Geographical Society of Halle, and proposes to compare the contents with the original diary, should the latter still exist.

M. MAYEFF, who was sent by the Russian Government for the exploration of the routes which lead through the land of Hissar and Amu-daria, has now returned to Tashkend. He has explored and surveyed the routes, 78 miles long, from Djam, a town south-west of Samarkand, to the great town Guzary; and two other routes from Guzary to the passage of the Amu river at Keliff,—one of them 98 miles long, and the other, through Shir-abad, 152 miles. The latter is the best, as there is plenty of fresh water and wood along the whole of the route, as well as two large settlements, Derbent and Ser-ob. At Keliff the Amu-daria is 1,170 feet wide, and steamers can go up the river as far as this place. There remains only 27 miles from Keliff to the Afghanistan town Akhcha, or Andho, and no more than 80 miles of a very good route from Akhcha to Sarypul.

M. PRJVALSKY, who returned some time since from his Central Asian travels, is now preparing for a second journey to Thibet, which was postponed because of the bad state of health of the indefatigable traveller, as well as because of the insecure diplomatic relations between Russia and China.

WE learn that the St. Petersburg Geographical Society and the Society of Naturalists are preparing a scheme for the scientific exploration of the little-known parts of the Caucasus.

THE principal paper in Guido Cora's *Cosmos*, Nos. xi. and xii., is a detailed account by Eugenio Parent of his voyage to Spitzbergen in 1872-73, in the Swedish vessel the *Polhem*.

AN expedition has been organised by the proprietors of the *Queenslander* newspaper for the purpose of making a flying survey of the territory beween Blackwall (Queensland) and Port Darwin, North Australia, a distance of 1,400 miles, with the view of determining the character of the country and the practicability of constructing a trans-continental railway. It was expected that the party would be fully equipped and start from Blackwall on July 12.

IT may be of interest at present to know that *Globus* is publishing the itinerary of Dr. P. Schröder's second journey in Cyprus in the spring of 1873.

AT Duisburg on Tuesday there was unveiled a memorial of Gerhardt Kremer, commonly known as "Mercator," and the author of "Mercator's Projection." Born of German parents in Flanders in 1512, he settled at Duisburg in 1552, and died there in 1594. The first stone of the monument was laid in 1869, but lack of funds delayed its completion.

BREHM'S THIERLEBEN[1]

THESE three fine volumes are in continuation of those reviewed in NATURE (vol. xvii. p. 43), and for the most part they maintain the popular and scientific character of this really great popular work. A. E. Brehm contributes all that was left of the mammalia, and gives a great volume on the reptilia and amphibia. The invertebrata have been wisely placed in the hands of Oscar Schmidt, of Strassburg, the insecta having been already completed by Teschenberg. A. E. Brehm's two volumes comprise nearly 1,400 pages, and they are about the average size of those which have appeared, but the invertebrata (without the insecta) are crammed into less than 600 pages. This is the only great fault we have to find, and it appears to be chronic in every country and under every editorship. The vertebrata take up so much space that the invertebrata must be "scamped;" and the "scamping" is the result not of the editors or authors, but of the publishers. Formerly this unfortunate elaboration of the idea of "first come first served," was limited to human history, and there is a well-known "History of England" which deals largely with the remote past, and which coming to the not unimportant reign of George III. at the close of the book, summarises it with the ejaculation, "whom God preserve!" We might, in a better spirit, say God bless some one who will do justice to the vast invertebrate sub-kingdom in a popular manner.

Oscar Schmidt has had a task of great difficulty to perform in giving anything like a general view of invertebrate life; and when the enormous advance of knowledge,

[1] Die Säugethiere, vol. iii., 1877; Die Kriechthiere und Lurche, vol. i., 1878, von A. E. Brehm; and Die niederen Thiere, von Oscar Schmidt, 1878. (Leipzig: Verlag des bibliographischen Instituts.)

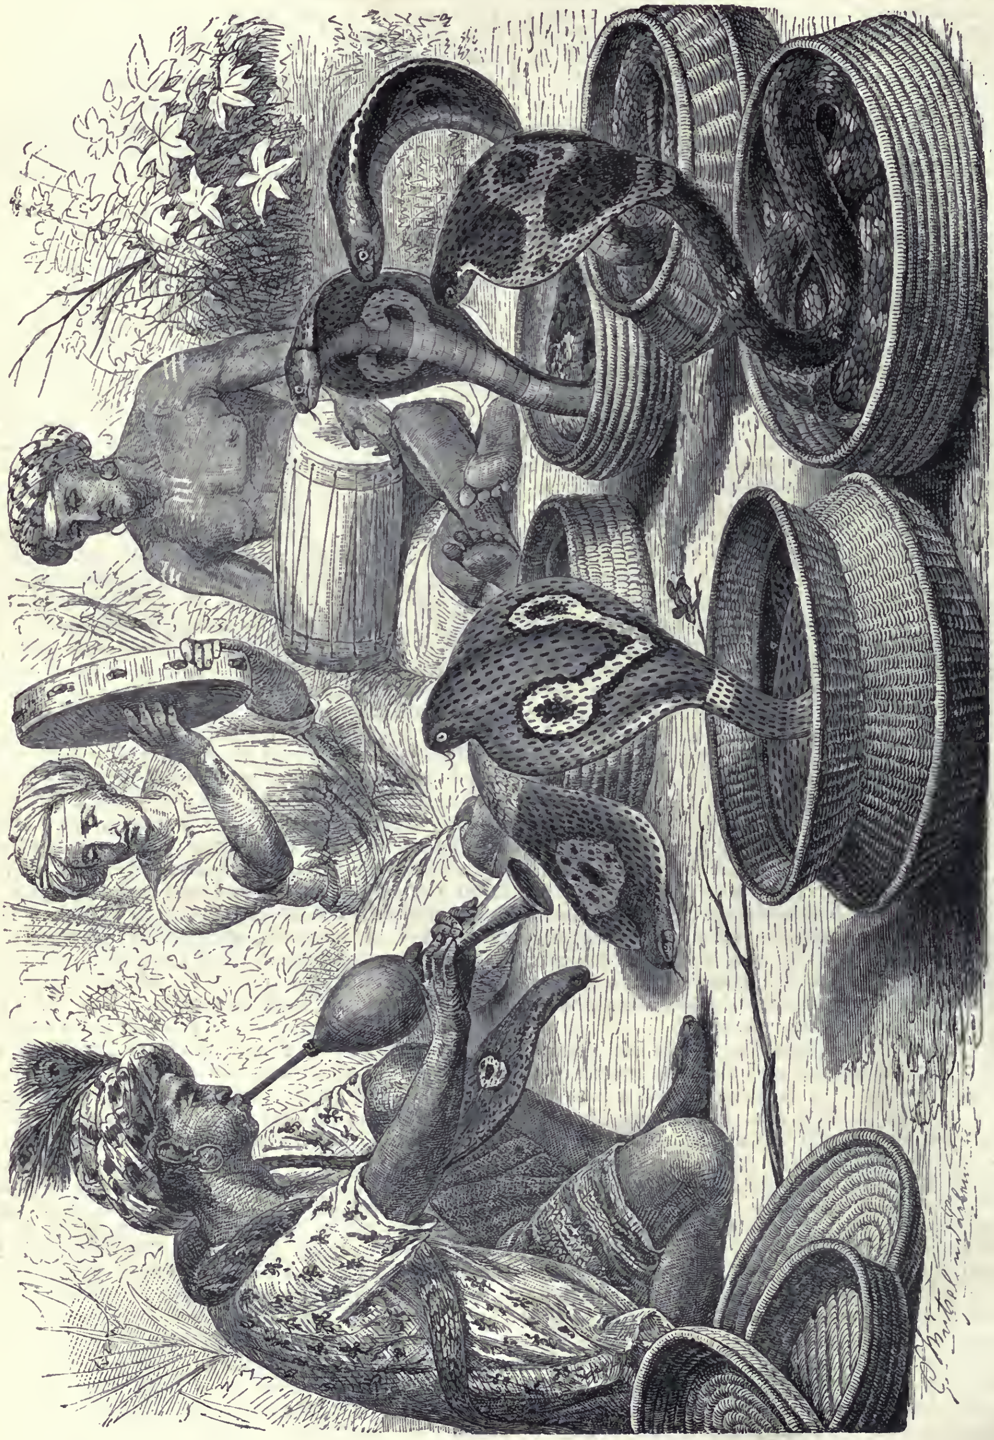
in many orders of it, during the last few years is considered, his contribution requires very equitable criticism. By choosing types of the great groups, by a free use of the observations and sketches made at the Naples and other aquaria, and by some happy selections of the results of the deep-sea dredgings of late years, a very presentable book has been put together. Nevertheless, the book will not satisfy the English reader who is likely to study it. Too good for the great mass of readers, it is so very deficient in the descriptive morphology and teleology of the lowest groups, especially, that the great want of the moderately-educated naturalist is not satisfied. The author's title-page dates 1878, but much of the best work of the world during the previous two years is not introduced. With regard to the authors who are quoted and utilised, there is a curious absence of some of the best English works, and the names of some of the most distinguished naturalists in the world are conspicuous by their absence. We protest very meekly, however, for it is good to be humble as the Germans were ten years ago, and when they did their best work and could think that their fellow-labourers who happened to differ from them were not absolute fools. Another peculiarity of this volume, is the highly diagrammatic nature of some of the views from the life; but it is compensated for by the elegance and artistic grouping of many of the objects in the larger plates, and by the introduction of many novelties. The book commences with the crustacea, the worms follow, the brachiopods and rotifera being in the midst, and the bryozoa concluding the group, and then come the *Weichthiere*, including the cephalopoda, pulmonata, prosobranchia, heteropoda, opistobranchia, and pteropoda. The bivalves follow, and then the ascidia. The great group of the echinoidea is despatched in twenty-four pages. The cœlenterata, including, according to the last morphological craze, the sponges, occupy less than one hundred, and the vast group of the protozoa less than thirty pages. Of this classification the less that is said the better; it is the age of novelties; but there are still some who do not yet fall down and worship the dross metal image Haeckel and others have set up. An interesting figure of the spider crab in its aquarium home gives the peculiar forward droop of the great claws and the daddy-long-legs appearance of the other members: and in another, one of the very opposite dromia group is bedecked with a sponge. A fine plate of pagurids shows one about to change its domicile and another with its usual sea anemone on its protecting shell. There are some interesting remarks on the parasitic amphipods, and the structure and the relations of *Phronima sedenteria* to doliolum and pyrosoma are noticed.

The smaller crustacea are illustrated by the life history and anatomy of Acanthocercus, and there is the queerest transparent *Leptodora hyalina* delineated; and it is to be hoped that it is more truthful than the Paradoxides on the next page but one, which has no facial suture, and whose cephalic shield is out of drawing. The chapter on the cirripedia is poor; and it would have been all the more complete if an abstract of the interesting paper on *Lepas fascicularis*, by poor von Willemoes-Suhm, had been given from the *Phil. Trans.* The successive nauplius stages, the cypris stage, and the absence of the Zoëa, were so splendidly worked out, that any modern natural history should contain them. On the other hand, the huge group of worms is very fully and ably dealt with. Nevertheless, it is to be hoped that some zoologist who may read Schmidt's *résumé* will speedily break it up into reasonable divisions, or rather separate and altogether reorganise the unwieldy, incongruous class. Amongst the rotifera *Notomata mysmeleo* is chosen as a type, and is carefully described and ably drawn from nature by Simroth, to whom the author is frequently under great obligation for exact and artistic illustrations. The exquisite Floscularia, however, is not satisfactorily given, and indeed to do so is hardly possible on wood. The five circum-oral prominences, armed each with a bundle of long protoplasmic filaments, which elongate and radiate, becoming like stiff hairs, and which diminish, become flaccid, and are retired as the creature contracts, are so well known to all observers of pond life, that good indeed must be the draughtsman who can faithfully convey the true impression. The parasitic worms are abundantly dealt with; but we miss the late researches on the land planarians. The general weakness of the chapter on the bryozoa is compensated for by the description and life-history of the extraordinary sponge-dweller Loxosoma, with its schwärm larvæ, and their metamorphosis.

Octopus vulgaris and *Eledone moschata* vie amongst the dibranchiata in ugliness in the illustrations relating to the cephalopoda, but there is nothing very new in the context. Amongst the shell-fish the most interesting forms noticed, are the heteropoda; and the gradation from the shelled Atlanta, whose description and delineation is very good, through carinaria and pterotrachæa to the naked phyllirhoe, resplendent with luminous spots by night, is well done. The pterotracheæ, so translucent and long and shell-less, with their tufted gills and absent tentacles, have evidently been carefully studied at the Naples aquarium, and all about them will be read with much interest. Doris and its neighbour *Ancula cristata*, and the extraordinary *Dendronotus arborescens*, are admirably given. There is much that will be new to the ordinary English naturalist, in the chapters on pteropoda, and the extraordinary larva of pneumodermon will excite as much attention as that of dentalium in the next chapter. Panceri's discoveries of the nature of the luminous organs of pholas are given, and the peculiar phosphorescent secretion is noticed. The chief merit of the chapter on the Ascidia is in the illustrations; but pyrosoma, with its wonderful luminous points, is well described, Panceri again being quoted from. The echinoderms are briefly treated, and the only two points worthy of notice are illustrations, one of urchins in the Neapolitan Aquarium, and the other of a comatula crawling over a sabella, with alternate legs, as is their wont. But there is a curious story in the context, relating to the fipssiarity of *Ophiactis virescens*, a six-armed Ophiurid. From this point the book is too short, and the important groups still unnoticed, are passed over too quickly. Beautiful engravings of hydrozoa, corals, and spongida abound, but the same cannot be said of those of the infusoria and amœba. Acineta is unlike nature, amœba does not show the peculiar head, and *Gromia oviformis* has its pseudopodia too moniliform; the last news about globigerina is not given. Finally, the drawing of the solitary radiolarian is wretched, and pretty noctiluca, with its vacuolated protoplasm, would have been all the better done if Allman had been studied and quoted. There are, however, very few shortcomings in this most interesting volume.

Dr. A. E. Brehm's volume on the reptiles and amphibia is magnificent, and combines good zoology with sufficient morphology and physiology, so as to make it a very useful book. Gustav Mützel, E. Schmidt, and Robert Kretschmer as artists have produced some wonderful plates, and the pages may be opened haphazard and good illustrations are sure to be seen. There is nothing harder to draw truthfully and artistically than a snake, and Mützel's *Morelia argus* (Python punctatus) on page 337 is the best realisation of a huge serpent on a tree-bough overhanging the water, and about to make its rush. When such ophidia partly cling, there is a remarkable flattening and angularity of the body at the spot; elsewhere the trunk may be as cylindrical as usual. This, so well known to the ancient sculptors, has generally been forgotten by modern draughtsmen, who generally draw a snake like a rope. In the instance before us, the truth is

carefully told with an able pencil, and the position of the head in relation to the first few feet of the body is admirably given. Without reflecting on British woodcutters, for they are for the most part beneath artistic contempt, the German engraving is often exquisite. A weird scene, where over water-lilies a moss-grown branch, half hidden in spiders webs and great orchid blooms, supports an angry *Draco rolans*, is capital. A butterfly is settling



COBRA CHARMING.

down within the creature's reach, but a fellow reptile has made its spring, and with expanded rib parachutes, is about to seize the insect's wing. The mimeticism of plant and animal is so fully developed by the artist, that really one must look hard at the picture before its faithfully rendered details strike the eye. A group of chameleons on a mimosa, one putting out its long club-ended tongue and the others glaring with their bulged

eyes and craftily creeping, is a capital picture to show a troublesome child, for it has the effect of a thorough scare. *Phrynosoma orbiculare*, with its sharp neck and back spines, the hideous moloch all bristling, ptychozoon with its fringes and odd-looking digits, are fairly comparable, in ugliness, with the chelonians, *Chelys fimbriata*, platysternon the big-headed, and the mischievous-looking snake-like tortoises—the hydromedusæ, and the artistic delineations and the descriptions are equal in merit.

The volume commences with a general introduction and then deals with the tortoises. It is interesting to find our White of Selborne quoted, in illustration of the habits of the common pet, and to notice that due credit is given to Darwin and Günther for their notices and elaborate

HORNED FROG.

descriptions of the gigantic land-tortoises. The flexible group are introduced by a description of cinixys, and then the terrapenes are described. Clemmys leads on to cinosternum, whose handy-looking beak, and active (for a chelonian) limbs, although small, give a very decided look to the animal. The turtles are noticed, and the curious dermatochelys completes the group. The crocodilia come next, and as it is the least popularly known, *C. acutus* strikes the reader at once. Its marine proclivities in and about San Domingo have so frequently been placed before the learned as indicative that the geological crocodilia were not necessarily fluviatile ani-

mals, that its habits, recorded by Humboldt, are very interesting. The sauria are commenced by a notice of hatteria, and it is to be hoped that by the next edition some one will have learned something of the habits of this extraordinary lacertilian with its dentate crest and back, palatine teeth, biconcave vertebræ, uncinate processes to the ribs and peculiar system of abdominal ribs—the living link with the oldest saurians. The Varanidæ and lizards are profusely illustrated, and Günther's work on pseudopus, more serpent-like, than Sincus in appearance, is noticed before this last genus. Trachysaurus, seps, and the Australian pygopus, might seem reasonably, from outside appearance, to lead to or to be parallel with Chirotes, with its small anterior extremities, and amphisbæna, and to merge into the ophidia. But Brehm has placed between the groups the highly interesting histiurus, chlamydosaurus with its ruff, uromastix, moloch the strange, basiliscus so heraldic in its contour, and the sea-lizard amblyrhynchus. There is a most comical drawing of two platydactyli meeting on a wall, one of them, the intruding party, clinging on to the steep face of a stone by its extended digits. These Gecko species conclude the part.

The ophidia have a very long and interesting introduction, which is more valuable in a natural history sense than in any other; the habits and archæology are capitally given, and some of the popular errors about snakes are exploded, commencing with the non-poisonous set, boa-constrictor and anaconda are given, the latter being rendered especially interesting by quotations from Bates, Humboldt, and Prince von Wied. Xiphosoma, a species of which, figured by Wolf in his usual style under Sclater's auspices, is familiar to us in England, has a spirited engraving by Mützel. It is disturbing the domestic felicity of a cock and hen, and chanticleer is grasped by the shoulder in the fangs of its enemy, whilst the hen is rushing off in dire alarm. The interesting long and slender snake from the Antilles is described with Brehm's usual care, and is drawn in its common position coiled up on a mass of sugar-cane leaves. Then passing on to the pythons, the author commences with a learned paragraph, in which quotations and opinions as to their size and gourmandising propensities are given from Megasthenes and Metrodus, whose vigorous imaginations were outdone by the boa seen by Regulus of one hundred and twenty feet in length. The snake which, in the time of Claudius, was found with a whole child in its stomach, comes nearer the truth. The Indian python (*P. molurus*) is shown strangling, in the folds of the first half of its body, a small ruminant, the hinder half being still on the ground to give a *point d'appui*. The hind-quarters of the prey are being grasped by the jaws preparatory to swallowing. A little further on *Python sebæ* is swallowing a bird: the gape is stretched to the utmost and the muscular tension of the neck is admirably given. There is a long and interesting history of the water snake (*Tropidonotus natrix*) with notices of its hybernation and habits, and the tree-snakes, well illustrated, lead to the water-loving and ugly Japanese achrocordus. The natural history of the poisonous snakes is carefully given, and the researches on the nature of the poison are carried down to the date of Brunton's and Fayrer's work. A large plate of the cobra charming is given. There is a wonderful drawing of *Hydrophis cyanocincta*, with its compressed body, and of the flat-headed, long-snouted sea-snake (*Pelamis bicolor*). There is much interesting information given about the vipers and the rattle-snakes, headed by a drawing of that curious happy family, the prairie-dog, owl, and snake, and the group ends with the genus Bothrops. In dealing with the amphibia, Günther is very generally followed, the hylidæ are elaborately illustrated, and *Nototrema marsupiatum* especially. The Antilles frog (*Hylodes martinicensis*), whose metamorphoses are shortened in the egg in which they have a very short tail, which is lost during the first day of liberty, is described, and then, passing on to the Ranidæ, the esculent form is noticed and figured. A pre-Raphaelite horned frog from the south of the Brazils, the obstetric alytes and the pipæ are admirably drawn and described. There is nothing very striking amongst the urodela, and the gymnophiona are curtly treated. There is no doubt that this volume will be studied by all who can read easy German, and we commend it to schoolmasters who usually teach the language out of the dreariest books.

The third volume of the mammalia, by Dr. A. E. Brehm, includes the horses, the ruminants, proboscidea; tapirs, rhinoscerides, hyracoidea, pigs, hippopotamidæ, and the marine series, and they are contained in nearly 700 large pages. The natural history of these groups is so profusely embellished with illustrations, and so replete with anecdotes relating to the habits, instincts, and methods of capture of the principal types, that it is a true popular encyclopædia of this part of nature. There might be more anatomy and physiology, but, as a book for common reading in all parts of the world, it is most excellent, and well up to the zoology of the day. It is refreshing to be reminded of the old school of zoologists, now almost extinct in this country, whose members, if they did not know all the anatomical minutiæ, the homologies, morphological affinities, and the terribly hard names of, and devoted to, the animal kingdom by modern *savans*, did know the outside appearance, and could tell interesting tales about the beasts of the field. It is true that they had not reached that standpoint where it is necessary to get at the base of the skull of a ruminant before its genus can be told, or to examine the knee, carotid, or some other *post-mortem* matter of a bird before it can be classified. But they could distinguish between living things by their outsides, and had a good idea of the notion of a genus and species from external characters. The horse, of course, affords great scope for Brehm's literary powers, and the archæology and the divisions of the group are well and carefully done. As everybody is the best possible judge of a horse, those who read this part will surely criticise the illustrations. They will please those observers who know the motions of a horse from plates, but they will not pass muster with horse-loving people. There is a cut of *Equus hemionus*, and, evidently from the position of the most prominent of the group, it is about to lie down at full gallop. Next comes a large plate of an Arab of pure blood, a stallion without a single good point about it: its ears are close together, it has small nostrils, and a jowl like a cart-horse; straight shoulders, small, long, upper fore-legs, and a great narrowing of the hock below the knee; it has a long barrel, no end of space between the rib and pelvis, and the off hind-leg is that of a rocking-horse. An Arab is admiring this beast, and an erect Black is probably discounting its value to that of twenty-five pounds. The tail is the best part. On p. 29 a mare and foal are trotting, and the mare is pointing her descending fore-foot after the manner of screws; artists rarely will see that the sound horse tries to get the back of its foot down in the trot, and then never falls. A cut of a quagga shows that this African animal does not require to touch the ground in its motion—motion we say, for whether the beast is trotting, cantering, or larking, it is impossible to say, for the near legs are wide apart, one under the nose and the other under the tail, whilst the off legs are within a foot of each other, and all are in the air. Burchell's horse is, however, properly drawn.

The ruminants will be more interesting to those readers who have not had the advantage of visiting large zoological gardens or of reading the stories of the great African hunters; but there are several types which are uncommon, and which are of much interest. There is nothing particularly new in the other groups, and the works of Murie, Brown, and others, have been carefully abstracted in dealing with the pinnipedia.

P. M. D.

THE PIKERMI AND SIWALIK FAUNAS PLIOCENE, NOT MIOCENE

THE best zoologists are in the habit of calling the mammalian fauna of Pikermi, in Greece, *miocene*. As instances, I may quote Mr. Wallace in the "Geographical Distribution of Animals," p. 118, where it is expressly stated that the mammalian remains in question are "from the upper miocene deposits of Pikermi," and Prof. Flower, in his paper "On some Cranial and Dental Characters of the Existing Species of Rhinoceros," P.Z.S., 1876, in which he mentions, p. 457, "the miocene *R. pachygnathus*, Wagner, from Pikermi."

I had occasion, a few days since, to consult Gaudry's "Animaux Fossiles et Geologie de l'Attique," in connection with the Siwalik fauna—also persistently, but, I believe, wrongly classed as miocene by European geologists and naturalists—and to my surprise I found it shown by the clearest evidence, that this Pikermi fauna occurs in pliocene beds, the age being proved by the occurrence of marine shells at the base of the bone-beds, and by the circumstance that the strata containing both bones and miocene shells rest unconformably on others with miocene plants. The latter fact is less important than the former, the value of plant remains for the determination of geological age being a disputed point, but no geologist hesitates to accept the indications afforded by marine annuals in preference to all others, and the tertiary marine faunæ of the Mediterranean area are particularly well known.

M. Gaudry proposes a hypothesis, *op. c.*, p. 431, to account for the presence of so many miocene forms in pliocene beds. It must not be forgotten that several Pikermi species are identical with forms found in undoubted miocene strata in Central and Western Europe. The theory proposed is briefly that the Pikermi mammals were driven into the hills by the breaking up of the miocene land, and starved to death, when their bones were washed down into the bed with pliocene mollusca. As there must have been, I think, a long interval of time between the deposition of the disturbed miocene beds and the formation of the unconformable pliocene strata, I think the following suggestion is preferable, as it avoids the idea of any sudden change. There is abundant evidence that the refrigeration of the earth's surface, culminating in the glacial epoch, commenced in pliocene times, and this may have led to a southern migration of the mammalia, so that animals which, in the earlier epoch, inhabited Central Europe, at a later period still survived in Grece, although they had been replaced by pliocene forms further north. It has already been shown by various writers that there is a connection between certain miocene faunas in Central Europe and the living mammalia of Africa on the one hand, and of the Malay countries on the other, and I think it not improbable that the remains found in pliocene beds in Greece, and at the base of the Himalayas, owe their miocene affinities to the same facts of migration to which similar affinities may be attributed in the living forms.

The evidence of the pliocene age of the Siwalik is simple. In Sind strata containing miocene marine fossils pass up into beds with a mammalian fauna, including some of the older Siwalik forms, such as *Mastodon*, *Chalicotherium*, *Dorcatherium*, &c., together with *Dinotherium*, *Hyopotamus*, *Hyotherium*, *Anthracotherium*, &c., which have never been found in the true Siwaliks. These Sind beds are apparently equivalent to the lower Siwaliks, which are unfossiliferous in the typical area. In the middle and upper Siwaliks, instead of the old forms just named, *Elephas*, *Loxodon*, cervine and bovine ruminants in abundance, and other recent types are found. Now, as the Sind beds cannot be older than upper miocene, the typical Siwaliks must be pliocene. The mammal *Bos* (*Bubalus*) *palæindicus*, found in the upper Siwaliks, occurs also in the Nerbudda alluvium, where it is associated with palæolithic implements. It is not credible that a mammalian species could have lived from miocene to post tertiary times.

The question of the true age of these later tertiary mammalian fauna is of such vast importance in the attempts now being made by many naturalists to work out the line of descent of living animals that I trust I may be pardoned for calling attention to the preceding facts.

W. T. BLANFORD

OUR ASTRONOMICAL COLUMN

SCHMIDT'S CHARTE DER GEBIRGE DES MONDES.—In the Introduction to the *Erläuterungsband*, accompanying Prof. Schmidt's lunar charts, he has given an interesting account of the progress of his great work, of the difficulties he encountered, and the assistance afforded him in a variety of ways, until the honourable and flattering conclusion. It was in the autumn of 1839, at his native place, Eutin in Holstein, that his attention, at first given to botany and zoology, was directed to the moon, by the circumstance of a copy of Schröter's work having come into his hands through a sale by auction. The engravings of the numerous craters and mountain-shadows made so strong and lasting an impression upon his mind that he appears to have resolved to make the study of the surface of our satellite the principal aim of his life. At fourteen years of age the possession of a small draw-telescope, constructed by his father, enabled him to commence his observations of the lunar features, and his first sketch was one of the well-known streaks of Tycho, made with this instrument, which was supported against a street lamp-post! A stand being subsequently provided, he began to draw whole phases, in which Mayer's charts were found of service. Thus he observed in 1840, his school studies, as he tells us, suffering thereby not a little. As so often happens in similar cases, young Schmidt's peculiar bent attracted the attention of one who had the disposition and the means to aid him, and State-Councillor Hellwag, a highly-educated man, with advanced knowledge of astronomy, provided him with a very perfect telescope by Dollond, and with it he observed at Hellwag's house. In July, 1841, he saw the moon for the first time in a large telescope, Petersen, assistant to Schumacher at Altona, having shown him the crater Gassendi and Bullialdus. He then learned first, as he says, the richness of the lunar formations, the more that he became acquainted at this time with the large chart of Mädler. In 1842 Schmidt went to Hamburg, and obtained access to the observatory under Rümker's charge; here, through the good-will of the director, he made use of various telescopes in furtherance of his lunar work during the years 1842-45. In June, 1842, he was also assisted by Herr Bartels, of Hohenfelde, near Hamburg, who allowed him the use of his telescope, and it was at this time that he made the earliest drawings which proved available in the construction of his great chart. In 1845 he went to Bilk, near Dusseldorf, the site of Benzenberg's observatory, but his progress was slow here, the principal instruments originally in the building not being then serviceable. During his residence at Bonn in connection with the observatory presided over by Argelander, this continued to some extent, the regular work of the establishment claiming attention; nevertheless in the period 1845-1853 he obtained sketches which proved of value, with written descriptions of many of the features of the moon's surface. On several occasions during this interval, by the encouragement of Profs. Galle and Bruhns, he had opportunities of making drawings with the aid of the Berlin 9-inch refractor. From 1853 to 1858, Schmidt had charge of the observatory of Herr v. Unkrechtsberg, an ecclesiastic at Olmütz, and here he undertook micrometrical measures for determining the heights of the lunar moun-

tains, &c. In March, 1855, visiting Rome, he made sketches with the large refractor of the Observatory of the Collegio Romano, and in the following month delineated many of the lunar landscapes with the telescopes at the Observatory of Naples. In December, 1858, he entered upon his present position as director of the Observatory of Athens, but from the state of the institution and the instruments, observations were not practicable for nearly a twelvemonth, so that it was only in November, 1859, that he was able to use, for his work on the moon, the 6-feet Plössl refractor, with which so much of the remainder of his long-continued labours has been completed.

In January, 1865, he formed the project of preparing a lunar chart, but his experience upon it for a considerable time was not satisfactory, for reasons which he details. In April, 1867, his final resolve was taken, and setting aside the results of his previous attempts at the construction of maps, he chose for his scale a 6-feet diameter, and, after the example of Lohrmann, arranged to subdivide his chart into twenty-five sections, as it has appeared. The work proceeded steadily until, in 1873 and 1874, those parts of it not strictly topographical and the colouring were completed.

In December, 1874, Prof. Schmidt proceeded to Berlin with his chart, for the purpose of exhibiting it to the authorities, astronomical and otherwise, in that capital. The interest which it excited here led to a fortunate combination of circumstances, through which the editing of the work was secured under the protection of the State, and the Crown Prince was instrumental in procuring the publication of the chart. At the suggestion of the Prince, the twenty-five sections were photographed in the department of the General Staff, and in April, 1875, Prof. Schmidt received from Field-Marshal Count von Moltke proofs of the same, which enabled him to bring the descriptive portion of his work to a close, while the original charts were retained at Berlin.

Such is a brief outline of the history of an astronomical undertaking that has occupied a lifetime. We must refer the reader to the explanatory volume for further interesting particulars of its progress and vicissitudes while under construction, at the many stations where its talented and indefatigable author has been located—from Altona to Naples.

NOTES

MORMONISM, whatever we may think of it as an institution, is so far in harmony with the times as to appreciate the value of scientific investigation; and its leaders seem to be heartily desirous to do what they can to further its interests. A recent number of the *Deseret News*, the leading organ of the Church party in Salt Lake City and Utah Territory, contains an account of the reception by President John Taylor, the successor to Brigham Young, of Dr. Thorpe, of the Yorkshire College, Leeds. Dr. Thorpe, accompanied by Dr. Schuster and Mr. Haskins, of St. John's College, Cambridge, is making a series of magnetic observations across the American Continent along the line of the Union Pacific Railroad, and Salt Lake City was selected as one of the stations. The president evinced considerable interest in the work, and showed a great desire to be informed respecting its character and objects. He offered to assign any spot within the city which might be deemed most suitable for the observations to the party, placed the transit instrument in the Tabernacle yard at their service, and suggested the laying of a special wire from his private telegraph office to the observatory for the purpose of exchanging time-signals with Prof. Safford, who is determining longitudes at Lieut. Wheeler's base station at Ogden. With such facilities the magnetic elements of Salt Lake City ought to be accurately known.

PROF. STRUVE, director of the Pulkova Observatory, is leaving Russia for a visit to Western Europe, for the purpose of giving directions for the construction of a new great refractor for the Pulkova Observatory. The old refractor, which some time ago was one of the best in the world, is now behind those of Washington, Chicago, and Gateshead (Mr. Newall's Observatory), and the Pulkova Observatory, according to the will of its founder, the Emperor Nicholas, should be maintained superior to all other observatories in that direction.

WE regret to announce the death, on August 15, at Kiel, of Prof. Emil von Asten, of the Pulkova Observatory, at the early age of thirty-six years. A pupil of Argelander, he is known by several remarkable researches,—as the investigation into the orbits of Uranus, and especially by his researches into the motion of Encke's comets with regard to the existence of a resisting medium. After ten years' study of the subject, he published a series of "Memoirs," in which he proved the existence of a medium, and showed why its influence could not be observed on other comets, as, for instance, that of Faye. His "Memoirs" have given rise, as is known, to one of those remarkable suggestions of Prof. Mendéleeff, as to the physical properties of this medium. Prof. Asten was, besides, one of the most valuable calculators of our time, and many of the Pulkova observations were reduced and calculated by him, or under his direction. His work on the sum of temperature, necessary for the development of several plants of the flora of St. Petersburg, was done during his leisure hours, as well as his discussions on the philosophy of Schopenhauer and Hartmann, of whom Prof. Asten was an admirer.

M. FIZEAU, the present president of the Paris Academy of Sciences, has been appointed to the Bureau des Longitudes, to fill the place vacated by the death of M. Leverrier.

WE have received the programme of a singular propaganda which seems to have been suggested by the recent opening up of the East to Western influences, and to which we cannot but wish all success. The circular is issued by M. C. Constant, of Smyrna, a member of the Asiatic Society of Paris, and his scheme is to form a society for the publication in Armenian of cheap popular scientific works, as one of the best means of enlightening and developing the people of the East, and of forming a bond of sympathy and union between those of all creeds. It is wished to implant in the East the great principles of the Experimental School, which form the greatness of the West. Special attention will be given to anthropology and the social sciences, which constitute the great problems of the age. The Eastern peoples are at a turning-point in their career, M. Constant says, and they ought to be prepared for the only definitive conquest to which they will submit sooner or later, "the conquest of science, that first European power." The proposed "Eastern Scientific Library" will be begun by the publication of an introductory volume treating of the positive method and its history; it will be a summary exposition of the intellectual evolution of humanity, from pre-historic times to the present. M. Constant makes appeal to the scientific societies of Europe for aid in this enterprise, and communications should be addressed to him as above.

THE Iron and Steel Institute holds its summer meeting at Paris this year, on September 16, 17, and 18, at the rooms of the Société d'Encouragement, 44, rue de Rennes. Besides the Introductory Address by the President, Dr. C. W. Siemens, papers will be read by Prof. Jordan, Paris, On the Mineral Resources of France; by Prof. Richard Akerman, Stockholm, On Some Studies Relative to the Present State of the Iron and Steel Manufacture, made at the Paris Exhibition; by Mons Euverte, Terre Noire, On Homogeneous Steel; by Danie Adamson, Manchester, On the Mechanical and other Properties of Iron and Mild Steel; by Mons. Marché, Paris, on Certain

Aspects of the Steel Manufacture; by J. S. Périssé, Paris, On the Ponsard Furnace for the Manufacture of Steel; by Sydney G. Thomas and Percy C. Gilchrist, Blenavon, on the Elimination of Phosphorus from Pig Iron in the Bessemer Converter; by R. P. Rothwell, New York, On the Low and Strong Water Gas Processes. Visits have been arranged for to the works of Creuzot, of Terre Noire, and of Hayange, Lorraine.

THE scientific facilities of Zürich are to be increased by the erection of a magnificent new chemical laboratory for Prof. Victor Meyer. For this purpose the cantonal government has granted an ample site and the sum of 600,000 francs, which amount will be increased by appropriations from the city. Prof. Meyer, although but 30 years of age, is one of the most popular and well-known professors of chemistry of the present day, and his present laboratory is thronged with students of various nationalities.

WE intimated some time since that a wealthy Danish brewer had set aside the sum of a million Danish crowns for the support of a laboratory in which to carry on scientific research. The first report of work done in this laboratory has just been issued under the title of "Meddelelser fra Carlsberg Laboratoriet" (Copenhagen, Thieles Bogtrykkeri). It is in Danish, with an abstract appended in French. The founder of the fund, from the application of which so much of scientific interest and technical value may be expected, is Mr. J. C. Jacobsen, a Danish gentleman who owns a large brewery in the neighbourhood of Copenhagen, and who is well known and honoured in his own country for his patriotism and for his intense love of science and art. The Carlsberg endowment is only the last of a series of munificent gifts to his country, or rather to the whole civilised world. The fund itself, as we have said, consists of one million Danish crowns, or about 56,000*l.* English. This sum is vested in the hands of five persons, who are nominated by the Danish Royal Academy of Sciences. A portion of the annual revenue is to be expended in keeping up the splendid laboratories attached to the brewery, in which chemical and physiological researches are carried on with a view to establishing as complete a scientific basis as possible for the great industries of brewing and malting. The other portion will, after the death of the donor and his wife, be expended in the advancement of the various natural sciences, mathematics, philosophy, history, and philology. In the administration of this latter portion much latitude is very properly allowed to the trustees of the fund, who will be enabled to apply it in almost any way they think proper. It becomes, in fact, a veritable research fund for all branches of science. The statutes of the fund will well repay a careful examination. The endowment has now been in force for something like two years, and the report embodies the results obtained in the laboratory during that period. The papers are of different degrees of value and interest, but on the whole form a very respectable contribution to our knowledge of the subjects on which they treat. A correspondent writes that last year he had the opportunity of inspecting the magnificent laboratories of Carlsberg, and was much struck with the complete and luxurious manner in which they are fitted up, and with the good style of work that was being carried on in them. The Report contains papers on the following subjects:—"On the rotatory power which beer-wort exercises on polarised light, and on its variations during fermentation," "Estimation of extract," and "Estimation of alcohol in beer," by M. J. Kjeldahl; "Researches on some factors which affect the propagation of the low yeast of *Saccharomyces cerevisiæ*;" "On the influence which the introduction of atmospheric air into fermenting wort exercises on fermentation;" and "Researches on the influence of temperature in the production of carbonic acid on barley germinating in darkness," by M. R. Pedersen.

MR. F. A. OBER, who has been engaged for several years in prosecuting investigations into the ethnology and archæology of the West India Islands, under the direction of the Smithsonian Institution, reached Martinique in the beginning of July, where he proposes to continue his labours. He has already explored the islands of Dominica, St. Vincent, Santa Lucia, Antigua, and Tobago, and has sent home a very good collection of the birds of these islands, including quite a number recently described by George N. Lawrence as new to science. He has also supplied many archæological objects of considerable interest. A list of the birds of Dominica and St. Vincent, prepared by Mr. Lawrence, is published in the *Proceedings* of the National Museum at Washington, and the notices of the remaining islands will soon appear in the same journal. Mr. Ober expects to return to the United States in September or October next.

A NEW meteorological society is in way of formation at St. Petersburg; its special aim will be the extension of meteorological observations in Russia.

THE committee of the Liebig Monument Association at Munich have given their decision regarding the various models sent in for competition. The first prize (100*l.*) was awarded to the sculptor, Herr M. Wagmüller, of Munich, and the second (75*l.*) to Prof. Begas, of Berlin.

THE International Association against the pollution of rivers, the soil, and the air, will hold its second meeting at Cassel on September 9 and 10, *i.e.*, two days before the meeting of the Association of German Naturalists.

THE general meeting of the United German Societies of Archæology and History will take place at Marburg on September 15-19.

AMONG the subjects expected to be discussed at the Social Science Congress at Cheltenham, October 23-30, are the expediency of increasing the number of universities in England, and the desirability of establishing free primary schools throughout the country.

THE Exhibition of Sanitary Appliances and Articles of Domestic Use and Economy, held in connection with the Autumn Congress of the Sanitary Institute of Great Britain, will take place at Stafford, from the 2nd to the 19th of October next.

AT Chalons-sur-Saone a committee has been formed for the erection of a monument in memory of Joseph Nicéphore Niepce.

IN the Fourth Report of the Underground Water Committee of the British Association, read at Dublin, Mr. De Rance comments on the scientific and practical importance of the continuance of the experimental well boring just carried to a depth of 1,000 feet, through the pebble beds of the new red sandstone, for the Liverpool Corporation, by Messrs. Mather and Platt. The boring is 26 inches diameter, and if continued, would not only prove the water-bearing capabilities of the new red sandstone, but its thickness, the character of the underlying rock, the nature of the coal-measures beneath, and the possible existence of productive coal-seams, and other questions of not merely local, but national importance.

AMONG the scientific novelties of the German book trade during the past month we notice the following works:—"Praktische Anleitung zum Bestimmen der Käfer Deutschlands und der Schweiz," J. Hoffmann (Stuttgart); "Vier Jahre in Afrika," E. von Weber (Leipzig); "Die Messung des Feuchtigkeitsgehaltes der Luft," Dr. K. Koppe (Zürich); "Theorie der Bewegung des Wassers in Flüssen und Canälen," O. Meissner (Bamberg); "Leitfaden der Physik," R. H. Hofmeis-

ter (Zürich); "Lehrbuch der vergleichenden Anatomie," Prof. A. Nuhn (Heidelberg); "Handbuch der Erdkunde," G. A. von Klöden (Berlin); "Beiträge zur Kenntniss der Orchideen," H. G. Reichenbach, Bd. 3 (Leipzig); "Die Alpenpflanzen nach der Natur gemalt," J. Seboth (Prague); "Die Rose; Behandlung, Zucht, und Pflege," Dr. A. Oehlkers (Leipzig); "Flora im Garten und Hause," H. Jäger (Hanover); "Anatomisch-physiologischer Atlas der Botanik," Dr. A. Dodel-Port (Zürich); "Lehrbuch der Botanik," Dr. C. Baenitz (Berlin); "Die Vögel," D. Kompfe (Leipzig); "Die Raubvögel Deutschlands und des angrenzenden Mitteleuropas," O. von Riesenthal (Cassel).

AT the recent Congress of Hygiene in Paris the National Health Society of London had three representatives. The National Health Society is composed of those interested in sanitary work of both sexes, and deals exclusively with matters affecting the sanitary condition of all classes, leaving medical questions to the doctors, and endeavouring to accomplish "prevention" rather than "cure."

Two guides and two German tourists recently lost their lives in ascending Cevedole, a mountain of the Tyrolese Alps. One of the victims was Dr. Sachs, the preparator of Prof. Dubois Reymond.

WE would direct the attention of our provincial readers to a useful article in this month's *Science Gossip* on "How to Start a Natural History Society." The directions are thoroughly practical and sensible.

ONE of the most interesting handbooks in connection with the Paris Exhibition is that to the British Indian Section, by Dr. Birdwood, the second edition of which is before us. It contains a great deal of geographical, antiquarian, and historical information, the Introduction treating of the geographical and physical features of the Indo-Germanic shore, on the Settlement of the Old World by the Human Race, the Antiquity of the Indian Trade, Routes of Indian Commerce, and of the Master Handicrafts of India. An Appendix contains much useful statistical information, and the handbook ought to be of permanent value.

THE *Cologne Gazette* gives details of the earthquake of August 26, as observed in that city. The earthquake passed from east to west. About three minutes to 9 A.M., a shaking and rising and falling of the ground, after the fashion of waves, began to be felt, and increased more and more until buildings rocked to and fro in a formidable manner. Tables, chairs, beds, stoves, &c., set up a dancing movement, which became so strong and tremulous that figures and ornaments resting upon them were knocked against one another and thrown down. Several persons declare that they felt as if an electric current were passing through their legs, and as if the earth were withdrawn from under their feet, and a sudden giddiness came over them. In some places the pendulums of the clocks ceased to beat. Towards the end of the vibration, which lasted about seven or eight seconds, there was heard a dull sound like the roll of distant thunder. Several persons state that soon after the first series of shocks there was a second but much lighter one. There was another (a third) shock at 11.10 A.M., which was not equal to the first either in severity or duration. It may be remarked that no fall of the barometer was observed to follow the earthquake. An interesting observation was made in the neighbourhood of Muhlheim on the Rhine:—"A very distinct curl was seen to cross the river obliquely, from south-south-west towards north-north-east, quite undisturbed by the current, while at the same time a deep roar of the water was heard. Even still (the afternoon of August 27) there is an audible rattling of the panes of glass, and domestic utensils, if close together, knock against one another, while a dull rolling sound is heard." The earthquake wave was felt from Hanover and Utrecht to Mayence in the south. The motion was sensible at Brussels and Liége, as well as Bonn, Cologne, and Aix-la-Chapelle. Some papers state that a seismograph at Cologne has proved the shocks to have had a duration of three-quarters of a minute.

IN the night of August 21–22 a meteor was seen to fall on a house in the vicinity of Butzbach, a small town in Hesse. On the following morning a small polished dark stone was discovered on the spot, and will be sent to the Berlin Museum.

IN consequence of the annexation of Alsace and Lorraine, the piscicultural establishment of Hüningen, which had been founded by the French government in the year 1852, passed into the hands of the German government, which, since 1871, has bestowed the greatest attention on the establishment, and spared no cost to make it as efficient as possible. Recent statistical reports state that the establishment, while under German control, has sent away no less than 23,500,000 ova of various species of fish, such as trout, salmon, carp, roach, &c. Some two million young salmon have been placed in the Rhine, and a similar number of other useful fish into the rivers of Upper Alsatia. The result has been that fish are now plentiful in those waters, that the rents paid for fisheries have considerably risen, that salmon can now be bought at about 6*d*. per pound in that neighbourhood, and that the time seems to have returned when fish was in those districts a cheap food for the people.

A NOTABLE improvement in watches is reported from Chaux de Fonds, Switzerland. By a peculiar process the figures on the dial are rendered luminous, so that if exposed once during the day to the sunlight they remain phosphorescent and visible throughout the night. Preparations are being made for the production of these watches on a large scale.

THE International Association for obtaining a uniform decimal system of weights, measures, and coins is holding a Congress in Paris at the Trocadéro this week. Though an unofficial gathering, several governments have sent representatives to it. On Monday, M. Tresca gave a survey of the question all over the world, and pointed out that the only countries which have as yet made but little progress are England, the United States, and Russia. It is thought the Congress will be able to agree on the general adoption of the metric system for weights and measures, and perhaps on a 10f. gold piece, nine-tenths fine, as an international unit.

AT the Birmingham Natural History and Microscopical Society's meeting on Tuesday last, Mr. Bolton exhibited the polyzoon, *Cristatella mucedo*, and the grouped rotifer, *Lacinularia socialis;* Mr. Slatter exhibited the polyzoa, *Fredericella sultana* and *Paludicella ehrenbergi;* and Mr. Levick exhibited the infusoria, *Actinosphærium eichornii* and *Spirostomum ambiguum*.

AN interesting series of experiments was lately instituted by Herr Muntz, in order to determine whether the living cells of the more highly organised plants, when entirely cut off from oxygen, are equally able, with the cells of fungi, to produce alcoholic fermentation. For this purpose he experimented with a variety of plants, beet, maize, cabbage, chicory, portulacca, nettles, &c. From each kind three equally healthy plants were selected. One was left in the open air, and the other two were placed with the accompanying soil, under capacious bell-glasses, containing an atmosphere of nitrogen, the oxygen being removed by pyrogallic acid. After a lapse of from twelve to forty-eight hours, they were removed from the glasses. One was placed in the open air in order to be certain that the power of development was retained after the imprisonment, and the other was cut off above the ground, distilled with water, and tested for alcohol. In all cases the plants which had been in an atmosphere free from oxygen showed appreciable quantities of alcohol, amount-

ing often to a thousandth of the entire weight of the plant, while no traces could be detected in the plant which had remained in the air during the same time. In this connection we should mention a detailed account in the *Journal für Prakt. Chemie*, of experiments instituted by Prof. Gunning, of Amsterdam, to settle the question of the ability of bacteria to exist in media free from oxygen. They consisted in inclosing in glass tubes easily decomposable substances, such as raw flesh, green peas, &c., infecting with a drop of a mixture of decayed peas and white of egg, which contains nearly all varieties of bacteria, —closing the tubes by fusion after freeing entirely from oxygen, and allowing to stand for periods ranging from four months to two years. The results of all these experiments showed that by exclusion of oxygen the bacteria were completely destroyed, the putrefaction being entirely stopped, and not continuing afterward, on the admission of filtered air free from bacteria.

THE appearance of phylloxera at Sachsenhausen, near Frankfort-on-the-Main, is officially reported. The appearance of the Colorado beetle at Jaratschewo in the district of Schrimm in the Prussian province of Posen is also reported.

AT Oderberg, in Austrian Silesia, we learn from a report to the Imper. Geol. Instit., March 19, some pile-structures, or rather the floors associated with them, were found in digging for the foundations of gas-works. Two rows of parallel, horizontal oak stems, 60 to 90 centimetres thick, 3½ metres apart, were met with. They were covered with peat, and a quantity of hazel nuts and seed of cereals lay under the peat. At 3 metres deeper more hard wood was found.

PROF. A. M. MAYER asks us to make the following corrections in his article on "Floating Magnets" in NATURE for July 4 (vol. xviii.):—On p. 258, 2nd col., line 13 from bottom, delete the sentence beginning "This is the only instance," &c. On p. 258, 2nd col., line 11 from bottom, for "This nucleus of 20 cannot be formed without the circumposed magnets as in Fig. 20," read "This nucleus can be formed without the circumposed magnets." On p. 259, 2nd col., line 11 from top, for "1*a*" read "8*a*."

THE additions to the Zoological Society's Gardens during the past week include a White-lipped Peccary (*Dicotyles labiatus*) from South America, a Golden Agouti (*Dasyprocta aguti*) from Guiana, presented by Mr. G. H. Hawtayne, C.M.Z.S.; a Bonnet Monkey (*Macacus radiatus*) from India, presented by Capt. Clarke; a Cape Bucephalus (*Bucephalus capensis*) from South Africa, eleven Spinose Lizards (*Agama colonorum*) from North-West Africa, received in exchange; a Common Marmoset (*Hapale jacchus*) from South-East Brazil, a Grey Parrot (*Psittacus erithecus*) from West Africa, deposited; a Red Deer (*Cervus elaphus*) born in the Gardens.

THE BRITISH ASSOCIATION

REPORTS.

Report of the Committee on Mathematical Tables.—Mr. James Glaisher has undertaken the calculation of the factor tables for the fourth, fifth, and sixth millions, similar to Burckhardt's and Dase's. Burckhardt's tables (Paris, 1814-1817) contain the least factor of every number not divisible by 2, 3, or 5, from unity to three millions, and Dase's tables (Hamburg, 1862-1865) give similar information for the seventh, eighth, and ninth millions. Dase undertook the calculation at the suggestion of Gauss, who urged him to begin at 6,000,000, as the three millions between 3,000,000 and 6,000,000 had been calculated by Crelle and presented to the Berlin Academy, and Gauss did not doubt that they would be published sooner or later. It appears, however, that the Berlin manuscript is too inaccurate to admit of publication, and therefore, in order to fill up the gap, it is necessary to undertake the calculation again, as the nature of the work is such that errors committed do not readily admit of discovery and correction. Mr. Glaisher has completed the portion from 3,000,000 to 4,039,500, which is ready for press, and the remaining two millions are being actively proceeded with.

Report of the Committee on Oscillation Frequencies of the Rays of the Solar Spectrum.—Mr. G. J. Stoney explained the objects of the Committee, and stated that in the table now published the oscillation frequencies of the principal rays of the visible part of the solar spectrum have been computed from Angström's determinations of their wave-lengths in air, combined with Ketteler's observations on the dispersion of air. Such a table and its accompanying map afford the most assistance that can be given towards the detection of harmonic relations, for rays that are harmonically related are therein represented in the simplest form practicable; in the table by an arithmetical series of the same type as the series of natural numbers, where the common difference is equal to the first term; and on the map by a series of equidistant lines.

Report of the Committee on Luminous Meteors.—Mr. James Glaisher read this report, which consisted of (1) an account of meteors doubly observed, with a table showing their real paths, velocities, and radiant points; (2) a detailed account of large meteors; (3) general directions and instructions to observers for recording meteors and aërolites, by Prof. A. S. Herschel; (4) the discussion of a meteor of short period (viz., the fireball of November 27, 1877, for which a short period, such as, say, 500 days, is found), by Capt. G. L. Tupman; (5) an elaborate analysis of the constituents of masses of meteoric iron and stone-falls, by Dr. W. Flight.

Report of the Committee on Underground Temperature.—Prof. J. D. Everett read this report. The principal novelty was the proposal to make observations in filled up bores by a thermo-electric method. Two wires, one of iron and the other of copper, each covered with gutta-percha, were to be joined at both ends, where a portion would be left uncovered. One junction would be buried in the bore, while the other would remain above ground available for observation. A current would flow through the circuit composed of these two wires whenever the two junctions were at unequal temperatures, and the observer would immerse the accessible junction in a basin of water containing a thermometer, and would regulate the temperature of the water until he found by a galvanometer that no current passed. He would then know that the temperature of the water as indicated by the thermometer was the same as that of the buried junction.

SECTION A.—MATHEMATICAL AND PHYSICAL.

Researches made at Dunsink on the Annual Parallax of Stars, by Prof. R. S. Ball.—The author stated that it was, of course, well known that up to the present time no parallax of a star had been detected which exceeded a single second of arc. In the great majority of cases the parallax was very much less, even if it was appreciable. But when they reflected that not one star out of ten thousand had yet been regularly examined for parallax it was obvious that it would be rash to conclude that there were no stars nearer to us than those of which the distance was already known. In selecting objects for investigation of annual parallax astronomers had generally chosen those stars which were exceptional either on account of their brilliancy or the largeness of their proper motions. Either of these features in a star afforded, doubtless, a *primâ facie* presumption that the star was comparatively near the earth. On the other hand, even Sirius had, according to Gylden, a parallax of only one-fifth of a second, while for another star, which had the enormous proper motion of seven seconds annually, Brunnow had found a parallax not greater than one-tenth of a second. The presumptions of nearness founded on great brilliancy or great proper motion, except, perhaps, in the case of 61 Cygni, could hardly be said to be justified by the results of observation. There was, however, a presumption that some of the red stars might be near the earth, and that some of the variable stars were really small, and therefore, as they were visible, comparatively near us. Before commencing the observations described and tabulated in the paper a working list was formed, containing red stars, variable stars, stars with large proper motions, and several other stars which were chosen on different grounds. The observations had the special object of seeing whether any of them had a large parallax. Forty-two different objects had been selected from this working-list, but in almost every case the observations con-

vinced him that the parallax was certainly less than one second, and most probably did not exceed half a second. It would therefore be understood that the results were purely negative so far as the immediate object in view was concerned, as they did not suggest the existence of any parallax worth following up. The principle upon which the reconnoitring observations were conducted was this :—The effect of annual parallax upon a star was to make the apparent place of the star describe a minute ellipse, of which the mean place of the star occupied the centre. The star was observed twice. At the first observation the star was at or near one of the extremities of the major axis of the ellipse; at the second observation it was at the other extremity —so that the observations were so arranged that in each case parallax would have the greatest effect it was capable of producing.

Lord Rosse gave a *Description of an Equatorial Mounting for a Three-Foot Reflector*.—The optical arrangements of the telescope recently erected at Parsonstown was exactly similar to that of previous telescopes, and it was only the mounting which was different. The wooden tube, however, which was formerly formed of staves, had been replaced by an iron tube, which was constructed after designs by Mr. Bindon Stoney. The leading peculiarities of the mounting were that the points of reversal were situated at the east and west instead of at the north and south. The bearings on which the instrument turned in right ascension were smaller than in the ordinary mountings. The motions in declination and in right ascension were effected by means of screws, so that on a windy night the instrument could not run away with the observer. The tube was square; the clock was connected with a strap, and the counterpoise was less than usual. The cage for the observer was independent of the mounting, moving on a circular rail, and with a second motion like that of a derrick crane. The only reflector of a similar size mounted equatorially was that constructed by Mr. Grubb for the Melbourne Government. Lord Rosse illustrated his explanation by means of models of his own and of the Melbourne reflector.

On the Stanhope "Demonstrator" or Logical Machine, by R. Harley, F.R.S.—Towards the close of the last century a logical instrument was constructed by Charles, third Earl of Stanhope. The present Earl found the instrument and some fragmentary papers on logic among the relics of his ancestor, and at the suggestion of Mr. Spottiswoode, placed them in the hands of Mr. Harley, who has made a careful study of them. Earl Stanhope (born 1753, died 1816) is known to science chiefly by his printing press, microscopic lens, arithmetical machine, the monochord, and steamboat. But of his logical speculations, which occupied his thoughts for thirty years, and of his curious contrivance for working logical problems, called by him the demonstrator, nothing has been known. The author did not attempt to give a complete or systematic exposition of the Earl's logical system; but he brought out those points which serve to illustrate the demonstrator as a means of performing logical inference. He noticed that Stanhope anticipated George Bentham, Sir W. Hamilton, George Boole, and others in the quantification of the predicate, and notably De Morgan's rule for the numerically definite syllogism. Stanhope states the rule as applicable to all syllogistic reasoning, and he constructed his demonstrator for the mechanical working of this rule.

On Edmunds' Electrical Phonoscope, by W. Ladd.—This is an instrument for producing figures of light from vibrations of sound. It consists essentially of three parts—an induction coil, an interrupter, and a rotary vacuum tube.

The action of the instrument is as follows :—Sounds from the voice or other sources produce vibrations on the diaphragm of the interrupter, which, being in the primary circuit of the induction coil, induce at each interruption a current in the secondary coil, similar to the action of a contact breaker, or rheotome; therefore each vibration is made visible as a flash in the vacuum tube.

The tube revolving all the time at a constant speed, the flashes produce a symmetrical figure, as the spokes of a wheel, as in the Gassiot's star.

The number of spokes or radii are according to the number of vibrations in the interrupter during a revolution of the tube, and the number of vibrations being varied to any extent according to the sounds produced, the figures in the revolving tube will be varied accordingly.

The same sounds always produce the same figures, providing the revolutions be constant. In case of rhythmical interruptions being produced in a given sound, as in a trill, most beautiful effects are noticeable, owing to the omission of certain radii in regular positions in the figure.

The uses of this instrument are the rendering visible of sounds and showing the vibrations required in their production, and is a mode of confirming by sight an appeal to the ear.

The phonoscope is the invention of Mr. Edmunds, partner in the firm of Ladd and Co., London, by whom it is manufactured.

On Byrne's Battery, by W. Ladd.—This is the invention of Dr. Byrne, of Brooklyn, U.S.A.—The chief features in this battery are a compound negative plate and a simple mechanical means for preventing polarisation.

The negative plate consists of the extreme negative element, platinum, backed up by a plate of copper to reduce the resistance, the copper being protected by a thin sheet of lead to prevent any local action that might occur owing to holes in the platinum, which might allow the exciting fluid to attack the copper, and a thicker sheet of lead on the back of the copper, which is japanned; so a plate in section would show as consisting of, first, a sheet of platinum, then thin lead, then copper, and last by the thick japanned lead, the whole being soldered together to form a solid plate. The batteries are built up with a zinc plate and two of the compound plates, the exciting fluid being a bichromate of potash and dilute sulphuric acid solution.

This battery would soon become polarised but for the injection of air between the plates, which action appears simply mechanical and not chemical, various gases producing no different effects.

When the air is pumped in the most extraordinary effects may be produced, the quantity being enormous, being more than double that of any other battery of the same size. It is much used in the States for surgical operations, its extreme portability and control rendering it peculiarly useful in this direction. The platinum loop can be raised to any temperature and kept at the same simply by the action of the foot on the bellows, leaving both hands at liberty for operating, there also being an entire absence of fumes or other disagreeable smells.

A battery of four small cells will heat nine inches of No. 16 platinum wire to redness.

There is also another form of this battery in which the platinum is platinised: the exciting solution is composed of one part sulphuric acid to ten of water. In this form no air is required to be pumped through the solution. This is used as a motor battery for driving sewing-machines. The inventor states he has driven a heavy Singer sewing-machine for eight hours a day at a cost of twopence, including everything. As yet nothing has been done in this direction in England.

Dr. Janssen gave an account of his method of solar photography, and exhibited some beautiful photographs of the sun, and Mr. G. J. Stoney explained his spectroscope of very large aperture. Mr. J. R. Wigham explained the quadriform group flashing gas light, as used at Galley Head Lighthouse, with illustrations, and also a gas gun, which might be fixed on a rock in the sea at a considerable distance from a lighthouse or a fog-signal station, and fired as often as required from the station, without the keeper leaving his post: a gas gun was placed in the college grounds, and was several times fired from the table of the room in which the section met. Prof. Haughton gave an account of his investigations on the sun heat received at the several latitudes of the earth, taking account of the absorption of heat by the atmosphere, and of his conclusions therefrom with regard to geological time.

The section was divided into two departments on the Monday and Tuesday. There were twenty-two mathematical communications which were read in the department of mathematics, including papers by Mr. Spottiswoode *On the Eighteen Co-ordinates of a Conic in Space*; by Prof. H. J. S. Smith, *On the Modular Curves*; by Prof. R. S. Ball, *On the Principal Screws of Inertia of a Free or Constrained Rigid Body*; by H. M. Jeffery, *On Cubic Curves*; by Mr. J. W. L. Glaisher, *On Certain Special Enumerations of Primes*, and *On Circulating Decimals*; by Mr. F. Purser, *On the Geometrical Treatment of Bi-circular Quartics*; and by Dr. Hirst *On Halphen's New Form of Chasles's Theorem on Systems of Conics satisfying Four Conditions.*

SECTION C.—GEOLOGY.

On the Influence of Strike on the Physical Features of Ireland, by Edward T. Hardman, F.C.S., Geological Survey of Ireland. —Although not often mentioned in geological works, the in-

fluence of strike in determining the lines of direction of the principal physical features of a country, is recognised by most geologists, but in few countries is the relation so distinct as in Ireland. The author was led to pay attention to this subject some years ago on reading Mr. J. F. Campbell's paper on the glaciation of Ireland,[1] in which that gentleman assumes that the south-west and north-east trend of some of the mountains of Ireland, *e.g.*, those of Donegal and Kerry, is due to the glacial action of a huge ice-sheet passing over Ireland from the south-west of Scotland. The author, after some years' examination, has found, however, that in most cases the trend of the hills, and course of rivers, &c., are determined by the strike alone, and wished to place the facts he had noted before the section.

1. *Mountains.*—The Donegal highlands trend to the south-west along the line of strike of the ancient crystalline stratified rocks. The basaltic plateau of Antrim follows in outline the windings of the outcrop of the underlying chalk, and consequently the strike of the basalt itself upheaved with it. The Mourne Mountains and Slieve Croob also coincide in direction with the stratified rocks on their flanks, except where joints or faults have given rise to minor lateral valleys, *e.g.*, Carlingford Lough. The same adherence to the line of strike is seen in the hills forming the flanks of the Wicklow Mountains; in the Kilkenny and Tipperary coal-fields; the Comeragh and Knockmealdown Mountains; and is most remarkably shown in that series of flexured carboniferous and old red sandstone rocks forming the hills of Cork and the Mountains of Kerry, the axes of which stretch from Dungarvan (co. Waterford) to Cape Clear, and Bantry Bay. The Reeks of Kerry are good examples. Its influence is again shown in the shaping of the high ground forming the Munster coal-field, and finally in the mountainous district of Connemara, although here in places obscured by the action of faults. The Twelve Pins, Muilrea, the mountains flanking Killary Harbour, and the country northwards around Nephin Mountain are striking examples. Toward the central plain the isolated mountains of old red sandstone and Silurian rocks rising through the carboniferous limestone, viz., the Slieve Bloom Mountains, the Devil's Bit, and the Galtees, conform to the same rule, the axis of strike and direction being parallel.

2. *Rivers.*—In the south of Ireland especially many of the rivers follow the windings of the strike. The Suir follows the line of strike for eighty miles, only beginning to cross it about ten miles from the sea. The Blackwater runs along the strike for seventy miles of its course, crossing it for only sixteen miles. The Lee is directed by the strike for fifty miles of its length, as is also the Bandon River for the greater part of its course, while the Shannon may be traced along the strike of the beds for by far its greatest distance.

3. *Inland Lakes.*—Most of the lakes are conformable to the strike in their greater outlines, the smaller details being determined by the jointage. Of these may be mentioned Lough Neagh, Loughs Corrib and Mask, Lough Erne—most notably—Lough Allen, Lough Derg, and the far-famed Lakes of Killarney.

4. *Sea Lochs, Bays, &c.*—The majority of these may be included—Lough Foyle, Belfast Lough, Strangford Lough, Lough Larne. The most notable examples are those on the south-west. Roaring Water Bay, Dunmanus Harbour, Bantry Bay, Kenmare River, and Dingle Bay. Also the mouth of the Shannon, Galway Bay, and Clew Bay. Farther north, the principal bays and indentations along the line of coast stretching from Broadhaven to Donegal; Killala Bay, Sligo Bay, and Donegal Bay, have been excavated in their great outlines along lines of strike.

In conclusion, the author pointed out that nature had adopted the least expensive method of working; since it is always easier to excavate along a line of strike than across the bedding. Usually cleavage, or incipient cleavage, is induced along the line of strike by the forces which upheaved the rocks, and denudation is most early effected therefore in this direction.

On the Correlation of Lines of Direction on the Globe, by Prof. O'Reilly, M.R.I.A.—The theory of correlation of the great lines of direction on the earth's surface had long been studied and applied, especially in mining; and had been generalised by Elie de Beaumont, and applied by him to the correlation of mountain chains with remarkable results, but his theory had found but little favour with English geologists. The author having been led to examine the question, based his system on angular relations actually observable in certain rocks, and in these he had found the angles 40° and 70° to bear a very important part. He gave details tending to show the relation of those angles to the main lines of direction on the surface of the globe, taking as a base line the east coast of Madagascar.

[1] *Quart. Journ. Geol. Soc.*, London, May, 1872.

On Hullite, a hitherto Undescribed Mineral from Carnmoney Hill, Co. Antrim, with Analysis, by Edward T. Hardman, F.C.S.—This mineral occurs in abundance at Carnmoney Hill, near Belfast, in the basalt forming the old neck of a miocene volcano. It has never before been described or analysed, and has been referred to on the Survey maps and in the Survey collections as obsidian, doubtless from its black colour and waxy lustre. In physical character it somewhat resembles the chlorophæite of Macculloch, but is entirely different in composition, which more resembles that of delessite. From this, however, it differs essentially in colour, hardness, and specific gravity, but it appears to belong, on the whole, to the ferruginous chlorite group.

Physical Characters.—Colour, black; hardness, about 2; lustre, waxy, but dull; before blowpipe, with difficulty fusible at edges to a black glass sometimes magnetic; very slightly affected by strong acids in the mass, but nearly entirely decomposed when boiled in powder, in strong hydrochloric acid, occurs filling and coating vesicular cavities in basalt of Carnmoney Hill, &c.

Chemical Composition.

Silica	39·43
Alumina	10·35
Peroxide of iron	20·72
Protoxide of iron	3·69
Protoxide of manganese	trace
Lime	4·48
Magnesia	7·47
Water	13·61
Carbonic acid	trace
	99·77

Formula—$(CaMgFe'')_3\ (AlFe''')_4\ Si_6O_{21} + 7H_2O$.
Specific gravity, 1·76.

SECTION D.—BIOLOGY.

Department of Zoology and Botany.

On the Stipules of Spergularia marina, by Prof. Alexander Dickson, M.D.—As is well known, certain genera of *Caryophyllaceæ*, of which *Spergularia* is one, are distinguished by the presence of stipulary appendages. On examining lately the stipules of *Spergularia marina*, I was struck with a peculiarity presented by them, which, if observed at all by descriptive botanists, has not received the attention it deserves on account of its remarkable character. The stipules are free from the petioles and wholly cellular in structure. From connation of those of opposite leaves they form interpetiolar stipules with more or less regularly, though slightly bifid, extremities. Lastly (and this is the important point), these stipules are united to each other round the backs of the petioles, so that a sheath is formed completely surrounding the axis and the two leaf-bases. This connation of stipules round the backs of the petioles is very interesting as being a rare phenomenon. Cases are not uncommon where the two stipules are connate on the inner side of the leaf-base, constituting the so-called "axillary stipule," *e.g.*, *Potamogeton lucens*, &c., or on the opposite side of the axis from the leaf, *e.g.*, *Ficus elastica*, *Ricinus*, *Astragalus alpina*, &c., constituting the "oppositifoliar" stipule; but the only reference to connation behind the leaf-base I can find is in the case of certain *Astragali*, by St. Hilaire, in his *Morphologie*. In those species of *Astragalus* which I have examined I have not seen any one in which the stipules are actually connate in this way; but in some, *e.g.*, *A. alopecuroides*, the bases of the stipules extend round the back till they meet—a condition just short of connation. In *Spergularia*, as we have seen, we have the interesting combination of the interpetiolar connation with connation round the back of the leaf. In *English Botany* I observe that the condition is fairly enough represented by the artists, but, as I have already indicated, the morphological peculiarity does not seem to have impressed itself on the botanical mind.

Dr. Bayley Balfour remarked that a good deal of confusion existed as to the application of the term stipule, and showed that in some cases it was applied to structures of very different

appearance, and perhaps even of varying morphological significance.

On the Inflorescence of Senebiera didyma, by Prof. Alexander Dickson, M.D.—When at Plymouth last August during the meeting of the British Association, I took the opportunity of examining *Senebiera didyma*, a weed which grows in great abundance on road-sides and waste places about the town, and I was much struck with a remarkable peculiarity to be observed in connection with its inflorescence.

The inflorescence is like that of the mass of cruciferous plants, racemose. The racemes are "oppositifoliar," and at first sight the arrangement seems to be analogous to that of the oppositifoliar inflorescences of *Vitis* or of *Alchemilla arvensis*, where the inflorescence is really terminal, but thrown to the side by preponderant development of a "usurping shoot," the axillary bud of the last leaf produced by the primary axis before ending in the inflorescence. This view seems further supported by the fact that of all the foliage leaves, that opposite the raceme is the only one apparently destitute of an axillary bud, which on the supposition would be represented by the "usurping shoot." If, however, the plant is more closely examined, a very remarkable condition is disclosed, one, indeed, which offers a morphological problem of considerable difficulty, and which, probably, can be effectually solved only by developmental study. The peculiarity consists in the constant occurrence of a solitary flower springing somewhere from the internode below the raceme either about half way down towards, or almost close to the level of the leaf below. So far as my observations go, the solitary flower is never quite as low as the level of the lower leaf. It might be supposed that from almost immediately above the second last leaf of the main axis, the bases of the terminal raceme of the "usurping shoot," and of the axillant leaf of that shoot had all become fused together. Now, although cases are known on the one hand, of adhesion between the base of a terminal flower and that of the usurping axis (*e.g.*, *Helianthemum vulgare*, Payer), and, on the other hand, between the base of an axillant leaf and that of the usurping shoot in its axil (*e.g. Sedum*, sp. Payer), we do not know of connation of all three together. It is possible, but I think improbable.

The view which, after careful consideration, occurs to me as most fully satisfying the conditions of this remarkable case, may be stated briefly in categorical form as follows:—

1. The racemose inflorescence is terminal and properly begins just above the level of the "second last" leaf. It would thus include the aforesaid solitary flower.

2. The raceme, after producing one ebracteate flower, produces at its second node a foliage leaf from whose axil the "usurping shoot" springs.

By such an explanation we can dispense with any cumbrous adhesion hypothesis such as I have indicated above. The peculiarity is that the main axis does not, *per saltum*, pass from the condition of a leafy axis to that of an axis of inflorescence, but begins by producing one flower and then developing a foliage leaf beyond which the series of flowers is uninterrupted. The "usurping shoot," as above indicated, represents the axillary bud of the foliage leaf by which the raceme is interrupted.

On the 6-celled Glands of Cephalotus and their Similarity to the Glands of Sarracenia purpurea, by Prof. Dickson.—Dr. Dickson pointed out that the peculiar 6-celled glands found on the external surface of the pitcher, both surfaces of the pitcher-lid, and both surfaces of the foliage-leaf of *Cephalotus* are very nearly identical in structure with the glands on both inner and outer surfaces of the pitcher of *Sarracenia purpurea*, which were originally described by August Vogl. Dr. Dickson suggested that the remarkable resemblance in this respect, taken in connection with certain correspondence in the details of the insect-trapping apparatus might suggest an affinity not hitherto suspected.

Exhibition of Plants of Isoetes echinospora.—Dr. Dickson exhibited specimens referable to this species which he lately found growing on muddy bottom among Potamogeton in about two feet of water in Loch Callater, Aberdeenshire. The plants were remarkable for the very slender and tapering character of the leaves which curve outwardly. The spores are very markedly echinate, and in diameter about one-fourth smaller than those of *I. lacustris*.

Dr. Moore, Glasnevin, exhibited remarkable specimens of an Isoetes from Lough Bray, co. Wicklow. They were of great size, much above the average of specimens of *I. lacustris*. Prof. Suringar and Prof. M'Nab suggested that it might be the same as the Italian species known as *Isoetes malinverniana*.

Mr. Britten exhibited, on behalf of Mr. J. H. A. Jenner, specimens of *Rumex maximus*, Schreb, from a new locality on the Cuckmere River, East Sussex. The specimen sent showed the various characters by which *R. maximus* can be distinguished from *R. hydrolapathum*, the species with which it has been confounded.

Dr. Bayley Balfour exhibited, on behalf of Mr. Sadler, specimens of *Salix Sadleri* and *Carex frigida* obtained at the beginning of August in Corrie Chandler, Aberdeenshire. These plants were discovered in 1874 by Mr. Sadler, and have not been met with again until this year.

Notes on Naiadaceæ, by Dr. Bayley Balfour.—Dr. Balfour more particularly described some of the peculiarities observed by him in the genus Halophila, an extremely interesting tropical phanerogamous plant.

Dr. Price, of Chester, sent for exhibition portions of the leaves of *Cardamine pratensis* producing numerous gemmæ.

On the Supposed Radiolarians and Diatomaceæ of the Coal-Measures, by Prof. W. C. Williamson, F.R.S.—Prof. W. C. Williamson called attention to the *Traquariæ* of Mr. Carruthers, found in the lower coal-measures of Lancashire and Yorkshire, with small spherical objects that observer believes to be radiolarians like those still living in existing seas. Prof. Williamson showed that the radiating projections with which these spheres are surrounded were not siliceous spines like those of the Radiolariæ, but extensions of a continuous membrane which enclosed the entire organism, and which therefore could not have the spicular nature attributed to them. He then demonstrated that within this external membrane is a second inner one, which latter is filled with numerous small vegetable cells, like others shown to exist in the interior of fossil spores and reproductive cryptogamous capsules, found in the same beds as those which furnish the *Traquariæ*.

These conditions are so different from those existing in any known recent species of radiolarian as to lead Prof. Williamson to reject the idea of their radiolarian character; whilst their close organic resemblance to some obviously vegetable conceptacles found in the same coal-measures suggest that the *Traquariæ* are also vegetable structures.

The mountain limestone deposits of some British localities contain a vast multitude of minute calcareous organisms which Mr. Sollas and other observers have regarded as radiolarians. These structures, however, seem to exhibit no satisfactory evidence of being so. In the first place these organisms are now calcareous instead of siliceous. It has been suggested that their siliceous elements were removed, and replaced by carbonate of lime, but this appears to be most improbable.

Prof. Roscoe and Prof. Schorlemmer agree in stating that they would require overwhelming evidence before they would be prepared to accept such an explanation of the present condition of these objects or of the fact of the substitution of carbonate of lime for silica, that such an explanation renders necessary.

Count Castracane has published an account of a process by which he reduced numerous specimens of coals to very minute quantities of coal-ash, and has stated that he found in these ashes numerous marine and fresh-water diatomaceæ. Prof. Roscoe kindly allowed one of his ablest assistants in his laboratory at Owens College to prepare analyses of a number of coals according to Count Castracane's method. The residual ashes of these preparations have been mounted microscopically by Prof. Williamson, and in no one of them can a trace of a diatom be found. Beyond stating the fact he is wholly unable to account for the discrepancy between his results and those of the Italian observer, so far as his present observations go, he finds himself compelled to conclude that we have no proof of the existence of radiolarians or of diatomaceæ in the British carboniferous rocks.

A short discussion ensued, in which Sir Joseph Hooker, Prof. M'Nab, and Dr. Bayley Balfour took part, the views expressed coinciding generally with those of Prof. Williamson.

On the Association of an Inconspicuous Corolla with Proterogynous Dichogamy in Insect-fertilised Flowers, by Alex. S. Wilson, M.A., B.Sc.—The majority of conspicuously-coloured flowers whose cross-fertilisation depends on their being easily seen by insects, are proterandrous. Such plants have their flowers placed in close inflorescences, as, for example, in Erica, Calluna, Vaccinium, Digitalis, Linaria, Gladiolus, &c., and occasionally the flowers are secund, or placed on one side of

the axis, thus becoming more conspicuous. In the indefinite mode of inflorescence the older flowers are placed at the lower part of the flowering axis; hence in the commonest form of inflorescence with proterandrous flowers, the lower flowers are in the second or female stage at the time when those in the upper part are in the first or male stage. In proterogynous dichogamy with indefinite inflorescence, the older flowers are in the second or male stage when the upper and younger flowers are in the female stage. In *Scrophularia nodosa* we have a plant in which proterogynous dichogamy is associated with an *inconspicuous* corolla. The stigma after fertilisation is removed out of the pathway to the nectar by the bending back of the style on the outside of the corolla, while the stamens straighten out to occupy the place formerly held by the stigma. The corolla is small and obscurely coloured, being greenish, tipped with brown. The inflorescence is lax, and the flowers scattered all round the axis. The odour of the flowers and the presence of a nectariferous gland shows that the plant is fertilised by insects, and not by the wind. Among such inconspicuously-coloured flowers, proterogynous dichogamy seems to prevail, just as proterandry is characteristic of brightly-coloured flowers. Hitherto it has not been shown how an entomophilous plant could advantageously possess a small uncoloured corolla, and be proterogynous. Watching the mode in which wasps visited the *Scrophularia nodosa* afforded the solution of the problem. The first flower visited by the wasp was the top one, and it passed irregularly downwards from flower to flower, and left the inflorescence by the lowest flower. Bees, when collecting honey, do the reverse, visiting the lowest flower first, and proceeding from flower to flower in regular succession from below upwards, leaving by the top flower. The order in which the flowers are visited is therefore of the greatest importance. In Gladiolus, for example, the bee begins at the lowest flower, and will deposit any pollen brought by it from a neighbouring spike, and as it passes upwards, it will get from the *upper flowers*, a fresh supply of pollen to apply to the lower flowers of another spike. In *Scrophularia nodosa* the wasps, which are less highly specialised as honey collectors, chiefly visit the flowers and proceed from above downwards, leaving the inflorescence with pollen from the lower flowers to apply it to the stigmas of the proterogynous upper flowers.

Wasps differ from bees in one important point, viz., that while bees are purely vegetable feeders, wasps add to a vegetable diet by preying largely on insects smaller than themselves. Throughout the animal kingdom carnivora are endowed with keener powers of vision and scent than vegetable-feeding creatures. That keenness of vision which enables a wasp to descry its prey at a distance, aided by its acute sense of smell, in all probability also enables it to discover these obscure flowers, without the guidance afforded by a coloured corolla, the materials that would be required for its production being employed more economically by the plant, just as in cleistogamic flowers. The wasp also gains an advantage, as it has a better chance of finding honey in these obscure flowers on account of their being easily overlooked by insects less highly endowed as regards powers of scent and vision.

Notes on Dimorphic Plants, by A. S. Wilson, M.A., B.Sc.—The author pointed out that *Erythræa centaurium* was probably dimorphic, as it exhibited heterostyly, and had two kinds of pollen-grains. *Silene acaulis* was shown to have three kinds of flowers, male, female, and hermaphrodite, thus resembling *S. inflata*, which Axel has shown to be triœciously polygamous.

Some Mechanical Arrangements Subserving Cross-fertilisation of Plants by Insects, by A. S. Wilson, M.A., B.Sc.—The plants considered were *Vinea minor*, *Pinguicula vulgaris*, and the foxglove, and the author described the various structural peculiarities in the different flowers.

THE FRENCH ASSOCIATION

As might have been expected, M. Krantz has been appointed president for the Congress of 1880; but, contrary to all expectation, the decision of the Council who had proposed Algiers as the place of the meeting for 1880 has been altered, and Rheims has been chosen by a large majority. This unexpected vote will create some dissatisfaction in the colony, where great expectations had been raised by the coincidence of the anticipated arrival of the Association and the celebration of the fiftieth anniversary of the conquest.

Dr. Janssen delivered, in the large room of the Sorbonne, a lecture on the present state of physical astronomy, which was completely successful; but it was deeply regretted that no direct news had come of the eclipse and the discovery of Vulcan.

A great *soirée* was given in the Conservatoire des Arts et Métiers, and M. Cornu delivered, in the large hall, an able lecture on Polarisation. The most important part of the display was a series of twenty Jablockhoff lights, exhibited in the gardens. The effect, although splendid, cannot be said to have been better than in the Avenue de l'Opéra and round the Arc de Triomphe.

A banquet of 200 covers was given on Thursday, at the Continental Hotel, to M. Bardoux, the future president of the Montpellier meeting, and present Minister of Public Instruction. On the following evening a great reception was held at the Ministry of Public Instruction, M. Bardoux having opened his *salons*, not only to the members of the Association, but also to the delegates of public schools now visiting the Exhibition at the public expense.

The Paris meeting, however, has been comparatively lost amongst the many special congresses which are taking place without interruption in the Trocadéro, and of which none attracts much public notice. Meteorology had its special congress, holding its sitting at the very same hour when the meteorological section of the French Association was deliberating. Although a large number of influential meteorologists had congregated, none of them could find the means of attending regularly both meetings.

No paper of real importance has been read in any of the sections.

In provincial cities the coming of the Association is always coupled with the inauguration of some public monument, library, museum, schools, &c. No similar ceremony took place in Paris, so that in that respect, as in many others, this thriving Association may be said to have lost a year.

M. Frémy, in his presidential address on soda and steel, traced the history of the improvements in the manufacture of these productions during the past century, showing that at every important stage science stepped in and pointed out the direction which practice ought to take in order to secure progress and success. Science was always at her post, ready to solve, to the advantage of industry, all the problems proposed to her. In showing the important services that science has thus rendered to industry and to the country, he wished to prove that in supporting men of science, by encouraging scientific production, we give to the country natural forces and accomplish a patriotic act. Blind and egoistic spirits have dared to say that science has no need of encouragement, that the true man of science forms himself all alone, that he knows how to triumph over obstacles, that the difficulties which he meets with are necessary trials which only arrest mediocrity, and that he who stops by the way, wanting the scientific inspiration, deserves his fate. Such affirmations are only maintained by those who have not known the difficulties of the scientific career, and who often owe their advancement to favour. We could, alas! cite many examples which prove that the most ardent and courageous man of science may be arrested in his labours by invincible obstacles. M. Frémy then referred in warm terms to the many generous individuals who in France have come to the aid of scientific research, and at the same time said it would be unjust not to recognise all the efforts which have been made in recent years by the state to maintain in France the higher scientific studies. Magnificent and well-endowed laboratories, new scientific chairs, the school of higher studies—these are some of the services rendered by the French government to science. But it is necessary to attract to these laboratories men who are capable of making good use of them, men who really possess the vocation for scientific research, and to prepare a scientific generation to succeed the present. M. Frémy then showed that the French Association might help greatly in promoting this service to science.

PROF. HAECKEL ON THE DOCTRINE OF EVOLUTION

On Thursday, August 28, a banquet was given to Prof. Haeckel, at the Grand Hotel, Paris, by a number of his admirers, on the occasion of his presence at the Paris meeting of the French Association. A congratulatory address was delivered in the name of the Reception Committee by M. Jules Soury, one of the Staff of the National Library, who said

that men of science were witnessing a secular movement of renovation in France as well as in Germany. Prof. Haeckel then gave an address, containing one of the most uncompromising statements of what he believes to be the logical consequences of his doctrine that has been given by any living evolutionist. We translate from the *Revue Scientifique*.

"The friendly support which I have received in your midst touches me more than I shall say, for it is not only the man and the works which he has been able to produce that you have wished to honour; our profound love of scientific truth, our philosophical beliefs, our faith in the theory of evolution and in that doctrine of descent for which I venture to say I have already fought well, this, gentlemen, is the secret of the sympathy which unites us to-day. I have seen with great joy in the meetings of the scientific congress how the theory of evolution has already, whatever may be said, penetrated the spirit of French *savants*. In the sections of Biology the theory of transformism has appeared to many speakers the only explanation of the phenomena of life which they have studied. The last consequence of that doctrine—the descent of man, not only from the apes, but from all the series of lower organic forms, has even been proclaimed and vigorously defended by M. de Mortillet in the Anthropological Section."

"Prof. Haeckel then proceeded to state the doctrine of the descent of man, so well known in connection with his name. "Certainly," he said, "man does not descend directly from any existing anthropoids. No serious naturalist has professed that doctrine, which has currency only among the general public and theologians. For a long time frivolous and ignorant people have found a subject of pleasant and innocent gaiety in the thought that we wish to pass them off as improved apes. No one dreams of this; but certain professors of philosophy, and a number of facetious preachers, nourish this prejudice, which brings them fine and easy successes. They do not seem to have any idea that they furnish the best argument in favour of that theory, if it is sustainable. Are not their *naïve* pride, their infantine vanity, weaknesses of character which the apes have left us as a legacy? There can be no doubt that man and the apes of the Old and New World are descended from a common ancestor.

"That which, sooner or later, will lead all good minds to transformist doctrines is the feeling, every day more profound among us, of universal causality, of development, of continuity in nature. The number increases every day of those who seek the truth, the whole truth, and who rest only in the clear vision of the universal connection of effects and causes.

"Reason, causality, mechanism, on one side; superstition, mysticism, teleology, on the other. The theory of evolution, which considers and embraces entire nature as one whole, has replaced final causes by efficient causes. This has already been accepted, at least by philosophical minds, the only ones of which we need take count, for the old doctrines of the final causes of the unwise, the immutability of species, sterility of hybrids, geological catastrophes and successive creations, the impossibility of spontaneous generation, and of the youth of man on the earth.

"We cannot say at what moment of time nor under what conditions the first living beings appeared at the bottom of the sea, but there can be no doubt that they have been formed chemically from inorganic carbon compounds. The primitive monads were born by spontaneous generation in the sea, as saline crystals are born of their mother-waters. There does not exist, in fact, any other alternative to explain the origin of life. He who does not believe in spontaneous generation, or rather in the secular evolution of inorganic matter, into organic matter, admits miracle. It is a necessary hypothesis, which cannot be ruined either by *à priori* arguments or by laboratory experiments.

"The time has arrived to replace the antique dualistic and neologicalconception of life and spirit by the monistic or mechanical conception of the universe. We have arrived at the boundaries of the old and new faith. Mystery exists, perhaps impenetrable; in any case, scholastic arguments will not pierce it. The doctrine of final causes has all the *naïveté* of the explanations which prevail among savages and children; the theories of Lamarck and Darwin have given the last stroke to that decripit doctrine. Modern morphology is irreconcilable, not only, I say, with the dogma of creation, but with that of a Providence or of a vague idealistic Pantheism, of the kind associated with the names of Hegel, Schopenhauer, and Hartmann. If there certainly exists in reality, as I have striven to show, an etiological connection between individual development and the development of ancestry, between ontogenesis and phylogenesis, the phenomena of human embryology are only *mechanical* and necessary effects of the evolution of our remote ancestors, conformably to the laws of heredity and adaptation.

"Seventy years ago, permit me to remind you, the great Lamarck created the theory of descent, which Darwin, half a century after, was to develop by fecundating it with his doctrine of selection, founded on the physiological properties of heredity and adaptation. Goethe had also conceived that doctrine very philosophically. For it is the honour of our conception of things to have seduced philosophers, poets, and critics, such as Kant, Goethe, and Strauss.

"These great and noble geniuses saw imperfectly, gentlemen, that which we see better to-day; I mean to say that the theory of evolution is only a particular case of the most vast of cosmical hypotheses, that of the transformation and conservation of the physical forces. This is what the best minds, the most judicious and wisest, such as the eminent naturalist of Montpellier, of whom France ought to be proud, Prof. Charles Martins, now admit with entire good faith. According to Prof. Martins, in fact, "the theory of evolution binds together all questions of natural history, as the laws of Newton have bound together the movements of the celestial bodies. *That theory has all the characteristics of the Newtonian laws.*"

"Certainly, the laws of life, morphological laws, the laws of transformation of living beings, under the influence of adaptation and heredity, of selection and vital concurrence, are not susceptible of the mathematical rigour of the laws of astronomy. We cannot, however, doubt that they exist, as we do those of psychology, ethology or science of character, and social science. It is, I think, somewhat *naïve* to insist, as is often done, on the numerous anomalies which are observed among living human beings. These anomalies are only apparent as are perturbations in astronomy. If we possessed all the elements of these morphological laws, the solution, at least in part, of which I have at heart, we should see that these apparent anomalies are explained by the general laws of mechanics. No one denies that the extreme instability of the elements constituting the woof of organised beings renders biological problems of an infinite complexity.

"Our mission—to which we have succeeded after the great heroic generation of *savants* of the eighteenth century—for they were heroes, gentlemen, and the greatest of all perhaps, the Laplaces, Lavoisiers, Kants, Lamarcks, Frederick Wolffs—our mission to all, naturalists, physiologists, physicians, philosophers, linguists, historians, is to continue those traditions of powerful thought and manly love of liberty which made our grandfathers almost the equals of those Greeks of Ionia and Attica whom we venerated in our infancy as the fathers of all human science."

PROF. NORDENSKJÖLD ON THE COMPOSITION AND COMMON ORIGIN OF CERTAIN METEORITES [1]

PROF. NORDENSKJÖLD on comparing the composition of the meteorites which fell at Ställdalen in Sweden on June 28, 1876 (NATURE, vol. xvi. p. 238), with that of a number of other meteorites, has found that a remarkable similarity, if not identity, is disclosed by excluding the larger or smaller quantities of oxygen and sulphur which enter into their composition, and taking into consideration only the metallic constituents, irrespectively of their being oxidised or not. This similarity in composition is found to exist between various meteors, which, according to the common method of giving the results of analyses of meteorites, that is, by stating separately the metallic iron, sulphide of iron, soluble and insoluble silicates, &c., appear to be of quite dissimilar nature and composition. The meteorites compared are:—

I. Erxleben, 1812, April 15, analysed by Stromeyer.

II. Lixna, 1820, July 12, analysed by A. Kuhlberg.

III. Blansko, 1833, November 25, analysed by Berzelius.

IV. Ohaba, 1857, October 15, analysed by Bukeisen.

V. Pillistfer, 1863, August 8, analysed by Grewingk and Schmidt.

VI. Dundrum, 1865, August 12, analysed by Haughton.

VII. Hessle, 1869, January 1. *a*, analysed by G. Lindström,

[1] Abstract of paper in *Trans.* Geol. Union of Stockholm, 1878, No. 44.

pieces of a large stone; *b*, average of two analyses by Nordenskjöld of whole stones, weighing 1,063 and 0·64 grm.

VIII. Orvinio, 1872, August 31, analysed by L. Sipöez. *a*, chrondritic ground-mass; *b*, black connecting mass.

IX. Ställdalen, 1876, June 28, grey ground mass, analysed by G. Lindström.

Composition of Meteorites, excluding the Oxygen, Sulphur, Phosphorus, and Chlorine found in them.

Every one who has had experience of the analytical examination of meteorites, which is often very difficult, or at least tedious, writes Prof. Nordenskjöld, and who knows the difficulty of obtaining any proper average sample on account of the preciousness of the material, will perhaps see that here the question is no longer concerning an accidental similarity in the figures obtained, but an actual identity, showing that all those meteorites which have fallen in the course of more than fifty years form a natural group having a common origin. I have not yet been able to treat in the same way all the accessible analyses which, when those that are quite trustworthy are only in question, are less numerous than is commonly supposed. I consider it certain that it will be possible to arrange several other similar natural groups, and that very many other meteorites than those here enumerated belong to this group, which perhaps may be called Hessleites after the most abundant, most completely examined and analysed meteor fall.

It appears to me highly probable that all Hessleites belonged either in a completely metallic or in a *fully* oxidised condition to the same swarm of meteors revolving in our solar system, and that the differences in composition now exhibited by the meteorites belonging to the same group depend on changes to which the meteorites were afterwards subjected by being heated under the influence of oxidising or reducing substances.

With respect to the group now in question it is clear, from the microscopic structure of these meteorites, that the metallic iron forms their most recent constituent, and that it has thus arisen through reduction of the ferriferous silicates.

Where has this reduction proceeded? Probably not in the atmosphere of our globe, though the carboniferous substances which occur in a great number of fire-balls may very well form the necessary reduction material; possibly on the exploded heavenly body, of which these meteorites, according to a sufficiently hazardous and probably incorrect hypothesis, may form fragments; most probably, perhaps, in passing the perihelion, during the revolution of the meteor swarm round the sun.

That, besides, both reducing and oxidising influences, if on a smaller scale, make themselves felt during the short path of the meteors in our atmosphere, is shown on the one hand by the shining iron particles which are often found on the surface of the meteorites, and on the other hand by a comparison of the analyses of the large and small meteorites from Hessle; for while the large contain a considerable quantity of sulphur (1·88 per cent.), the small are nearly free of it (containing only 0·18 per cent.), clearly for the reason that the sulphur in them has been oxidised and driven off.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

FROM the Twenty-fifth Report of the Science and Art Department, we learn that the number of schools examined in 1877 was 1,348, the number of pupils under instruction being 55,927. These numbers are smaller than in 1876. This decrease was entirely due to the withdrawal of physical geography from the list of subjects for which aid is given; for in the remaining subjects a substantial increase had taken place. The subject added to the list when physical geography was withdrawn, viz., physiography, has already secured a large amount of attention; and it is probable that no less than 5,000 candidates will present themselves for examination in it in May next. The above-mentioned 1,348 schools comprised 4,635 different classes, from which 32,112 students came up for examination in May, in addition to 3,230 self-taught students and pupils in classes not taught by certificated teachers. From the results of the examination it is seen that the number of papers passed compares favourably with the statistics of previous years. The number of candidates who came up in honours was 1,029, of whom 85 passed in the first class and 192 in the second class. From the reports on the general character of the examinations which have been received from the examiners, it appears that the results of the examinations are generally of an encouraging nature. Some of these reports contain very valuable suggestions as to methods of teaching, &c., and they have been printed and circulated among the schools. The number of competitors for Whitworth Scholarships in 1877 was sixty-eight. Of these nineteen of the most successful in the theoretical subjects of competition were admitted to go forward to the examination in practical workmanship, which was as in previous years, held at the workshops of Sir J. Whitworth and Co., in Manchester. The Committee of Council state that they have received from the Council of the Royal Society a report of the work done by the gentlemen to whom grants had been made during the year 1877–78 out of the vote of 4,000*l*. for research. This vote was first made in the year 1876–77, the correspondence with reference to it being given in our last, the Twenty-fourth Report, at p. 7 of the Appendix. But owing to the period of the year at which the vote was finally sanctioned, the recommendation of the Council of the Royal Society was not received till March 16, 1877, and only 2,195*l*. 1*s*. 6*d*. came into payment out of that vote, the remainder being returned to the Exchequer. Considering the nature of these inquiries and the time necessarily devoted to preliminary experiments, it was not to be supposed that there would be much definite result to show in the first year. But on the whole very satisfactory progress has been made, and much good work already accomplished, several valuable papers having been contributed to the Royal Society.

WE would draw the attention of teachers in London and its neighbourhood to the admirably organised teachers' classes at St. Thomas Charterhouse School of Science. The session commences on the 28th inst., and those wishing for information should apply to the organising secretary, Mr. C. Smith, at St. Thomas Charterhouse Schools, Goswell Road.

AT a recent meeting of the council of the Yorkshire College, the following appointments were made:—As Lecturer in German and Oriental Languages, Joseph Strauss, Ph.D.; as Lecturer in French, John Willis, Ph.D. Both the new lecturers will commence their duties with the coming session, in October.

WE have received a very elaborate programme of the mathematical courses for the session 1878–9, under Prof. Sylvester, at Johns Hopkins University, Baltimore. Other circulars give a similar announcement in respect to the courses to be followed in languages, chemistry, physics, and biology.

THE University of Helsingfors will celebrate the fiftieth year of its existence during this autumn. The Finlandic University was originally at Abo, and was transferred to Helsingfors in 1828.

THE University of Zürich has just bestowed the title of Doctor of Jurisprudence on a young Russian lady, who obtained the highest honours in her examination for this degree.

AN institution for the higher education of ladies will shortly be opened at Kieff.

SOCIETIES AND ACADEMIES

LONDON

Entomological Society, August 7.—H. W. Bates, F.L.S., F.Z.S., president, in the chair.—A communication was read from Mr. M'Lachlan to the effect that, in the writer's opinion, the larva referred to by Prof. Westwood at the last meeting of the society, as boring in the stems of the potato, was in all probability that of a *Noctua-Gortyna flavago*, polyphagous in the stems of a variety of herbaceous plants.—Mr. S. Stevens exhibited some living specimens of *Teretrius picipes*, parasitic on

[1] And potash.

Lyctus oblongus, and also specimens of *Pachnobia alpina*, bred from pupæ found on the highest parts of mountains about Rannoch, N.B.—Mr. Enoch exhibited some remarkable varieties of British lepidoptera.—Mr. Rutherford exhibited some living specimens of an ichneumon (identified by Mr. F. Smith as *Cryphus formosus*), parasitical on the larvæ of a West African moth, allied to *Anapha panda*.—Mr. Rutherford also exhibited a series of colour varieties of the African butterfly, *Aterica meleagris*, as illustrative of the principles of protective assimilation and of some remarks he contributed thereon.—Mr. Jenner Weir exhibited five remarkable specimens of *Argynnis paphia*, and contributed some remarks on melanic variation in that species.—Mr. Wood Mason read a paper on the difference between the form of the antennæ in the males of *Idolomorpha* and other genera of *Empusidæ*, a sub-family of Mantidæ.—Mr. Dunning read a paper on the genus *Acentropus*.—The following papers were also communicated:—Descriptions of several new species of myriopoda of the genera *Sphærotherium* and *Zephronia*, by Mr. Butler; and descriptions of new genera and species of South American *Eumolpidæ*, chiefly from the Amazon region, by Mr. Baly.

GENEVA

Physical and Natural History Society, February 21.—Prof. Marignac having transformed into nitrates the gadolinite earths for the purpose of decomposing them afterwards by heat, obtained, after many successive experiments, products more and more pure, showing the existence of a third earth—terbene. The yellow tint of its oxide does not result from the presence of didymium in this oxide.—Prof. Soret described the principal results of his researches on the ultra-violet absorption spectra. Most of these spectra are continuous up to a given line, from which the radiations are more and more obstructed. The bases and the acids generally carry their absorbent properties into the salts which they compose.

March 21.—Prof. Alph. de Candolle read a memoir on the appearance and the falling of leaves of trees. He was not able to discover any direct and regular connection between the periods of the two phenomena. Among the species seen, individuals present great differences in this respect; we find sometimes that individuals earliest to get their leaves in spring are latest in autumn to lose them, but the exceptions to this rule are numerous. One specimen presenting singularities in this respect preserves, in general, its qualities from year to year (see *Arch. des Sc.*, t. lxii. p. 143).—Prof. Brun spoke of the causes of the movement and of the different modes of reproduction of diatomaceous algæ, which multiply by subdivision and by spores, and which live in the most diversely situated localities in the Sahara, as at altitudes of 2,600 metres in the Alps.

April 4.—Prof. F. A. Forel has studied the sculptured pebbles on the strands of the Lake of Geneva. Some are incised by a larva of the species *Hydropsyche*, others are covered with a tufoid incrustation, underneath which the calcareous stones are deeply sculptured. The incrustation results from the action of two algæ, *Enactis calcivora* and *Hydrocoleum calcilegum*.—M. Victor Fatio presented the report printed by him on the International Congress on Phylloxera at Lausanne, entitled "State of the Phylloxera Question in Europe in 1877."

April 18.—M. Alph. Favre read a note on the mode of formation of some stratified mountains and some valleys, which he explained by the ramming or lateral crushing of the geological strata. He has made experiments tending to prove his theory, by means of caoutchouc stretched out and covered with potter's clay, left to contract gradually. (*Arch. des Sc.*, t. lxii. p. 193.)—Prof. Soret, by means of the observation of the ultra-violet absorption spectra of gadolinite earths, has confirmed the conclusions of M. Marignac and M. Delafontaine on the existence of terbene and of another yellow earth besides terbene and yttria.—M. Arthur Achard indicated a peculiarity in the action exercised by a magnetic pole in a circular closed current. If we imagine the pole approaching nearer and nearer the plane of circumference by projecting beyond the latter, there will be an angular situation for which the component perpendicular to the plane of the current, from the action exercised by the pole on the latter, changes its sign. It follows that two opposite poles, the one on this side, the other on that of the situation thus defined, will exercise on one and the same circular current concordant actions.

PARIS

Academy of Sciences, August 26.—M. Fizeau in the chair.—The following, among other papers, were read:—Employment of the right ascension of the moon, corrected from tabular errors, for determining longitude at sea, by M. Faye. He indicates some modifications by which the errors in Hansen's tables may be corrected.—Comparison between the salivary and the sudoriparous glands, relatively to the way in which they are affected by section of their excito-secretory nerves, by M. Vulpian. Jaborandi still acts on the sub-maxillary gland several days after section of the excito-salivary nerves, whereas this plant, or its alkaloid, pilocarpine, from the sixth day after section of the sciatic nerve (which seems to contain all the excito-sudoral fibres of the posterior limb), has no longer action on the sudoriparous glands of the corresponding limb. M. Vulpian thinks the probable reason for the dissimilarity lies in the enormous quantities of nerve-cells, isolated, or in ganglionic groups, distributed throughout the secretory nerves which go to the sub-maxillary gland. These, after section of the nerves, probably prevent the fibres gradually losing their excitability as far as their peripheric extremities.—On the vibratory forms of solid and liquid bodies (third memoir), by M. Decharme. He finds that on circular plates (thrown into vibration) the breadths of the striæ are inversely proportional to the square roots of the numbers of vibrations of the corresponding sounds.—On pelletierine, an alkali from the bark of the pomegranate, by M. Tanret. Its mode of preparation and its properties are described; also the proportions got from the bark of different parts (most is got from the dry roots). Pelletierine is the tænicide principle of the pomegranate, not previously isolated.—Researches on strychnine, by MM. Gal and Etard. By causing hydrated baryta to act on strychnine under certain conditions, two new bases were obtained: they are called respectively, *dihydrostrychnine* and *trihydrostrychnine*.—Researches on the relations existing between the weights of the bones of the skeleton of a buffalo, by M. de Luca. The entire skeleton weighs about 29 kilogs. The lower jaw weighs a fifth of the cranium; the head (without lower jaw) as much as the vertebral column; the pelvis four times the sacrum; the bones of the head a fourth of the skeleton, the cervical vertebræ, the dorsal, and the lumbar, with sacrum and caudal vertebræ, about equal; the bones of the two anterior limbs double the posterior; the bones of the right side weigh more than the corresponding bones of the left. Of the vertebræ the atlas weighs most; the weight then diminishes on to the last dorsal, then increases and is stationary in the lumbar vertebræ; in the caudal the weight diminishes progressively, &c.

THURSDAY, SEPTEMBER 12, 1878

OUR NATURAL HISTORY COLLECTIONS

THE question of the government of our Natural History Collections, to which we have more than once called our readers' attention, has been taken up, we are glad to say, by the British Association. It was moved in the Committee of the Biological Section by Dr. Allen Thomson at the Dublin meeting, and carried unanimously, that the attention of the Council of the Association should be called to the fact that in the Act lately passed to enable the Trustees to move the natural history collections to South Kensington, the recommendations made by the Royal Commission on Science as to their future government have been wholly ignored, and that the Council should be requested to take such steps in the matter as they might deem expedient. This resolution having likewise successfully passed the ordeal of the Committee of Recommendations, and having been adopted by the General Committee of the Association, will come in due course before the Council, who will, no doubt, take decided action upon the question. The Royal Commission on Science having been appointed mainly at the instigation of the British Association it is not likely that the Council will suffer some of its most important recommendations to be thrown overboard without remonstrance. Meanwhile we may be allowed to offer a few more observations upon this subject, which, we need hardly say, is of the utmost importance as regards the future progress of biological studies in this country.

The great object to be aimed at is the complete separation of the new museum of natural history, both as to control and as to finances, from the Secretariat of the Trustees in Bloomsbury. If this point can be assured it does not so much matter whether the nominal governorship is vested in the Trustees or in a Minister of State. We may well believe that the main object of the Royal Commission on Science in recommending the latter course was to make sure of a divorce of the new institution from the Secretariat in Bloomsbury, under whose blighting rule the natural history collections have so long languished. It must be recollected that the so-called "Superintendent" of the Natural History Departments in the British Museum has hitherto held merely a titular office, so far as authority goes. He can neither spend a sixpence nor deviate in the slightest degree from existing practice without reference to the "Principal Librarian," who is the sole executive officer of the Trustees, and through whom all communications from the different departments have to pass. What is now necessary in the interests of natural history is that the Trustees should (as a minimum) be required to appoint a different executive officer for the new museum of South Kensington, and to keep its finances altogether separate from those of the British Museum. If this change can be effected there will be no longer any temptation to starve the natural history in order to pamper the library, as is the natural instinct of the "principal librarian," who is always selected from one of the library officials, and is utterly ignorant of the requirements of natural history over which he reigns supreme.

Not only should an independent director be appointed for the new museum at South Kensington, but he should be appointed at once. It may at first sight appear rather extravagant to assign a highly-paid director to a museum before there is anything or any person in it to direct, but in the end this will turn out to be by far the most economical plan. If the appointment of a director be deferred until the fittings of the new building have been finished, and the time has arrived to move the collections, it will be found that there will be all sorts of alterations required which will cost large sums. If the director be appointed at once there will be one person responsible to see that the fittings are such as will be suitable for the arrangements of the new institution, and the architect will have one definite person to consult upon the almost endless details which are necessarily incident upon the conservation and exhibition of such a varied mass of material as composes the National Museum of Natural History. We do not doubt, therefore, that many thousands of pounds would be saved by the immediate appointment of a responsible director. Who that director should be is perhaps a more difficult question. A few years ago the recommendation of the Royal Commission on Science that the present superintendent of the Natural History Departments of the British Museum should become the first director of the New Museum of Natural History, would have been the obvious course to pursue. But time runs apace, and it may be doubted whether the present superintendent would now care to undergo the fatigues and anxieties involved in the arduous task involved in the transfer and re-arrangement of the natural history collections in their new site. But there is another distinguished naturalist less advanced in years and already domiciled in South Kensington, whose appointment to such a post—if he could be persuaded to undertake it—would command universal assent. We need not mention his name—it is in every one's mouth.

One other point in connection with the new museum requires immediate attention. The sapient officials at the British Museum who planned the removal of the natural history collections never appear to have realised the idea that nowadays a library is a necessary appendage to a museum. We are told, indeed, that there has been no space even reserved for a library in the new building at South Kensington. But, as every naturalist knows, the collections would be simply useless in their new site without a scientific library. To execute any scientific work without books would, in these days, be more impossible than the famous, if now somewhat antiquated, task of making bricks without straw. But how is a library to be provided? It is not possible to go into the market and buy such an article off-hand. Many, even of the more modern works on natural history, are out of print, and can only be picked up from second-hand booksellers at long intervals. If, when the trustees determined on the removal of the natural history collections ten years ago, they had set apart 1,000*l.* a year out of the 10,000*l.* which they devote to the purchase of books, to form a special library for the Natural History Departments, the required library would have been now ready. But nothing of the sort was thought of, and as books on natural history are growing scarcer every year in consequence of the

increased demand for them, it must be now *many years* before the necessary library can be provided, even if there is an unlimited grant of money provided for the purpose. In the meanwhile, how is the scientific work at South Kensington to be carried on? In the first place the "Banksian Library," as it is called, which originally came to the British Museum along with the natural history collections, should be transferred along with them bodily to South Kensington. This will provide a good set of the older publications on natural history for the new institution. In the second place for the modern publications, which are of still greater importance, we venture on a suggestion—which will, we fear, make the principal librarian's hair stand on end—namely, that all the works and periodicals habitually used in the four departments of natural history should be temporarily sent on loan to the new institution at South Kensington. They should be returned to the British Museum by degrees so soon as duplicates of them can be obtained by purchase out of a fund to be annually devoted to the purpose. In this way the work at South Kensington might be carried on without interruption, and the National Library at Bloomsbury would at the same time suffer no permanent loss. It would be no doubt an occasional inconvenience to the readers at Bloomsbury to find that some of the books they require for reference are at South Kensington. But this inconvenience will diminish year by year, as the new set of books is purchased, and by this plan alone, as far as we can see, can the whole of the important scientific work performed in the natural history departments be prevented from coming to a standstill. In point of economy also there can be no question of this plan being the best, as the attempt to purchase at once all the books required for the new Natural History Museum would raise the value of them twenty-fold. Convenience and economy are therefore alike on the side of our suggestion, although we fear that it will be bitterly opposed by the principal librarian and his satellites, who object strongly to see the Banksian Library being removed from the hallowed precincts of Bloomsbury.

THE FENLAND

The Fenland, Past and Present. By S. H. Miller and S. B. H. Skertchly. (Wisbeach: Leach and Son. London: Longmans, Green, and Co., 1878.)

THIS book is practically the joint production of several, many chapters being contributed by writers whose names do not appear on the title-page, though given at the head of their respective chapters. The work contains about 650 octavo pages and is therefore cumbrous; it is divided into fifteen chapters, very unequal both in length and merit, which embrace a wide range of subject, including, among others, dissertations on History, Geology, Botany, Zoology, Archæology, Biography, Engineering and Sanitary Problems, &c. The printing done at Wisbeach has not been carefully revised, as shown by a long list of corrections, which however call attention to but a very small proportion of the errors. Many of the illustrations are presented by patrons, and these are fairly good, except the chromo-lithographed frontispiece which is very inferior either in workmanship or drawing.

The book, whatever its excellence may be in other respects, is certainly objectionable in its treatment of those subjects on which discussion is far from closed among men of science. A vein of dogmatic infallibility is particularly apparent in dealing with geological problems. The book, including so wide a scope, is evidently intended to pass into the hands of readers the majority of whom are quite unacquainted with geology, and to bid for support in this manner from the general public, instead of appealing to those who from their own experience would be able to estimate its real value for views and claims not yet recognised by fellow-thinkers and workers, seems unworthy of science. When original work is laid before specialists, the theories built upon it may be stated boldly and decidedly; but in a popular book, intended for the general reader, that which is accepted as fact and that which is still under discussion or not yet argued, should be distinctly separated, and in the latter case the relative value of each kind of evidence should be clearly defined. Too frequently of late the result of others' work has been incorporated by writers and set forth as their own and in a positive manner not claimed by the discoverers themselves. In this case we have not an account of the geology of the Fens, but an exposition of the opinions of Mr. Skertchly and others on geological questions, introduced as undisputed fact. It is questionable whether the readers to whom the book appeals care for or expect individual opinion, but would not rather desire an easy "coach" to the ascertained facts of Fen-geology.

To illustrate, we select first the treatment of Prehistoric Man. We are told that the "Old Stone Folk" —the term is preferred in the book to Palæolithic—are concluded to be related to the living Esquimaux, and that Prof. Boyd Dawkins is of opinion that they are lineal descendants. This inference, based as it is on very slender grounds—is the only foundation for the following positive assertion, made a few pages further on:—"The Old Stone Folk, on the other hand, belong to the Mongoloid class of *Leiotrichi*, of whom the Lapps and Eskimos are modern examples; hence we see that even in the Old Stone age there were no signs of the fusion of the crisp-haired *Ulotrichi* and smooth-haired *Leiotrichi;* and it is from such striking facts that we are justified in ascribing to mankind an antiquity far greater than that of the earliest relics at present known." It is needless to point out that so far from there being any reason to suppose that Palæolithic man was differentiated, the sameness of type—differing only where different material is used—of all the oldest stone implements is evidence against it. Where so much is predicated of the "Old Stone Folk," it is not surprising to find the "Newer Stone Folk" are minutely described even to their complexion and eyes as if they were still a living tribe. They are termed Iberian, which, as explained not to mean a people indigenous to or even coming directly from the Iberian peninsula, is a misleading term, and has no advantage over that of Black Kelt. The Basque people may be descendants of Neolithic man, but Neolithic men were not Basques. To say that they were a Turanian people means nothing more than that they were not Aryan.

The third chapter, by Mr. Miller, is devoted to a historic sketch of the Fenland people from the time of the Kelts

to the reign of Henry III., and is written on naturally surer ground and the interest is better sustained. The stories of the Saxon and Danish conquests are well told according to the most modern versions, and introduce the newest approved spelling of historical names. We can almost follow the exact steps by which the Normans took possession of the Fenland and how they kept it by building fortress dwellings, simply massive round or square towers, which the more civilised Saxon noble would never have made his home. This chapter is illustrated with engravings of coins and of one of the rare British circular bronze shields.

Chapter IV., on Language, and Chapter V., on the Dissolution of Monasteries, are also by Mr. Miller. Chapter VI., by Mr. Skertchly, treats of the attempts made to drain the fens, a subject well worked out by Sedgwick and his scientific assistants. The author's views, although probably correct, are put very decidedly, and in places plentifully sprinkled with notes of exclamation. The following from p. 158 will serve to illustrate the style :—

"How can it be shown that these districts on the same level, with interweaving watercourses and co-equal desiderata, were so distinct that they should be set at variance like a trio of mongrels over a meat biscuit? Yet such has been the disastrous result."

It appears to be Mr. Skertchly's opinion that the one essential to an engineer who undertakes drainage works is to understand "Mr. Tylor's laws" (Mr. Alfred Tylor, F.G.S.). In Chapter VII., a continuation of the last, the writer goes out of his way to object to the *absurdity* of the use of the time-honoured expression, "lands watered by rivers." Yet the term is right, for a land of many rivers is more moist and watered than a land without, and rivers do literally *water* the lands through which they flow. They do it by percolation, overflow, and mist. For instance, not only does the Nile, but rivers all over the world, the Thames itself among them, water their level lands by flood at certain seasons, by mist at night.

The Wash, a subject on which we naturally looked for a good deal of information, is too briefly disposed of in a chapter of only five pages. The next, on Meteorology, is sixty-seven pages long, and bristles with tables which in a popular work would have found a more appropriate place in the Appendix, since their presence in the middle of the work cuts it in two. The botanical sketch by Mr. W. Marshall would have been more welcome had it been longer, and we should have been glad to have seen more of the Fen rarities illustrated. The history of the spread of Anacharis is likely enough to be the correct one, but why is the name of the plant in the illustration *Elodia canadensis*, and *Anacharis alsinastrum* in the text. The Fungi, although not very numerous, have appropriately a section to themselves. It is strange that the writer should speak doubtingly of the occurrence of any fungi in the Carboniferous, since their presence there is now a well known fact. The eleventh chapter treats of the prehistoric fauna of the Fenland, and is so full of errors that it is to be regretted that, as in other instances, a specialist was not intrusted to write it. Space will only permit to notice a few of the inaccuracies. At p. 326, Hipparion is said to be "a horse-like animal with antlers like a stag," and this is the whole description. The table, p. 327, is not a complete list, and we know on the authority of Prof. Boyd Dawkins, that it contains besides, a number of species which have not hitherto been found in the beds to which they are ascribed; it separates *Ursus ferox* and *priscus* which are synonyms, and persists, which is the case throughout the book, in calling Lemmus, "Lemnus." The table at p. 328 is a marvel of careless spellings, none of which are included in the list of corrections at the beginning of the book, which we are "earnestly requested" to make with pen and ink. In another table *Bos brachyceros* is said to be "a variety" of *B. longifrons,* although these are admittedly synonyms.

The limits of a review, however, compel us to pass on at once to the chapter on Geology, with which especial fault is to be found. In the first place, from the nature of the book it is evident, as already intimated, that it is not intended to be specially consulted by geologists, and the fact that a survey memoir on this district, in which Mr. Skertchly was concerned, had already appeared, renders it quite unlikely that it would be. Mr. Skertchly recognises this by prefacing his subject with a perfectly elementary treatise on the science. Instead of this circumstance inducing him to guard his statements with more than ordinary care, he absolutely revels in the opportunity of airing his infallibility, as if without fear of contradiction. The theories of those whom he mentions as friends are everywhere brought in, those of his opponents mostly ignored. Thus Evans's "Ancient Stone Implements of Great Britain," a work in which implements from the Fenlands have been described, is not even alluded to, although the author appears to have made use of it. General readers should in fairness have been cautioned that Croll's theory is not supported by geological evidence, thousands and thousands of feet of consecutively deposited strata showing no trace of cold periods, much less of glaciation; that Geikie's theory of an ice sheet is not generally accepted by the Geological Society, as even this session's discussions show; that Tylor's Pluvial periods have but few adherents. By the way, the Pluvial period is here ingeniously reduced to local showers produced by the evaporation of melting snow and ice, although Mr. Tylor himself disclaims for it all connection with ice action, and claims on the contrary that it was of great intensity and long duration. Mr. Skertchly is so fully impressed with the correctness of the view he happens to take of things that he announces that his alleged discoveries have made the Brandon Beds of "surpassing interest" (a favourite term with him), "for ever setting at rest the question of whether man did or did not exist during the great cycle of the glacial period." This climax is worked up to by pages of *ex parte* reasoning which non-geological readers are not in a position to follow. Considering that this evidence has not yet been brought forward in any scientific publication, and that his repeated promises to bring it before the Geological Society have not yet been kept; that Professors Hughes and Bonney purposely went over part of the ground with him and have publicly thrown grave doubts on the value of the evidence; that Professors Prestwich, Boyd Dawkins, Mr. Evans and others do not admit its value, and that at the Conference held last summer on the Antiquity of Man, the weight of evidence was rather against his interglacial age in England,—it is little less than wantonness, whether

the evidence, only known to himself, is or is not conclusive to him, to introduce it as undisputed fact in this manner in the present publication. After this we have not enough interest to read the remainder of the book, and besides it is so full of mistakes, as Urus for Ursus (p. 505), shorter for longer (p. 511), &c., that it is a wearying effort to understand in places what the author really means.

J. S. G.

AMERICAN GEOLOGICAL SURVEYS

Geological and Geographical Atlas of Colorado and Portions of Adjacent Territory. By F. V. Hayden, U.S., Geologist in Charge. (Washington: Published by the Department of the Interior, 1877.)

IN the magnificent Atlas just issued by the Department of the Interior we have the consummation and crown of all the labours which Dr. Hayden and his staff have carried on so triumphantly for the last five years, and of which they have already given us so much interesting and important information in a series of Annual Reports. Before examining the work from a scientific point of view, no reader can refrain from expressing his admiration of the style in which the Atlas has been produced by the United States Government. As a specimen of cartography, typography, and lithography, it is altogether worthy of the highest praise. For beauty and indeed sumptuousness of execution, it may be classed with those *livres de luxe* which from time to time have been issued from the National Imprimerie of France.

The Atlas consists of two series of maps, the one of a general, the other of a detailed kind. The first series, on the scale of twelve miles to one inch, comprises four sheets, each embracing the whole State of Colorado and part of the neighbouring territory. The first of these illustrates the system of triangulation adopted in the survey; the second shows the drainage system of the area; the third by a simple and clear arrangement of colours, exhibits at a glance the economic features of the whole region—the agricultural land, pasturage, forests, and woodlands, sage and bad lands, mineral tracts, and the portions rising above the limit of timber-growth; the fourth contains a condensed and generalised geological map of the same territory. Nothing can surpass the lucidity of expression and artistic finish of these maps.

The second series—twelve in number—is on the scale of four miles to one inch, and consists of six topographical sheets and six identical sheets, coloured geologically. The topographical details, though numerous, are so selected as not to neutralise each other, or mar the broad, clear picture which the maps were designed to be. By means of contour-lines of 200 feet vertical distance, the surface-configuration of the whole region is depicted as in a model. We can follow the lines of the broad valleys, of the deep, narrow cañons, and of the hundreds of minor tributaries which have scarped out their courses on either side. Here we look down upon a vast table-land, deeply trenched by stream-channels; there upon a succession of bold escarpments or mesas which bound the table-land and hem in the neighbouring valley. Huge mountain-ranges rising out of the plateaus are so vividly drawn that they seem to stand out of the paper. Yet no shading is employed. All the effects of inequality are produced by contour-lines, so faithfully set down that a single line may be tracked in its sinuous course along the whole of a mountain front until it comes out upon the table-land beyond. When will our map-makers learn to use this, the only true method for expressing the surface of a country? The best of our atlases are disfigured by strips of shading running across the map like so many caterpillars, to represent mountain-ranges. Even our Ordnance maps, so admirable in most respects, are sometimes so loaded with shading, that a steep hill-side only a few hundred feet high is made as black as our highest mountains, and the topographical names can hardly be read, even with a magnifying-glass.

But, above all, welcome are these six geological maps. In the previously published maps and charts accompanying the Annual Reports, only small detached areas were represented, and even from the careful descriptions of the various geologists of the staff it was hardly possible to frame a satisfactory conception of the geology of Colorado as a whole. Ever since the marvels of its deep gorges and vividly painted cliffs were made known, that region has possessed a high interest to the geologist. He has now the means of gratifying his desire for further knowledge. With the help of these maps and the two accompanying sheets of sections he can realise most satisfactorily every great feature of Colorado geology. The ancient Archæan ridge—the nucleus or back-bone of the American continent—may be traced running north and south nearly along the present hydrographical axis of the country. Flanking that ridge comes a series of palæozoic deposits, the oldest of which have been identified palæontologically with Silurian formations. Rocks, regarded as of Devonian age, overlap the Silurian beds, and repose against the ancient crystalline ridge on the south-west side of the San Juan Mountains. They are soon buried under later accumulations, and they seem to be of but local development, since in most places where the rocks are found in juxtaposition, the Silurian are directly succeeded by Carboniferous strata. These last-named rocks cover large tracts of country, running as bands round the Archæan area, and lying in basins across it. Far to the west where the Grand River has so deeply trenched the Utah plateau, the flat Carboniferous beds appear from under the brilliant red Triassic strata. The difficulty of drawing any line between Triassic and Jurassic formations in that region is again acknowledged on these maps, the lower red series being doubtfully assigned to the older, and the upper variegated deposits to the later system. Cretaceous rocks are abundantly developed, and cover a vast extent of territory. In particular they spread over the wide plateaux between the San Juan and Gunnisen rivers, and form the platform on which the enormous volcanic outbursts have been piled up from the West Elk Mountains southward into New Mexico. It is more easy to trace on these maps, too, the area respectively occupied by the Laramie, Wahsatch, Green River, Bridger, and Uintah formations which represent post-cretaceous and tertiary times. Glacier moraines, lake-deposits, drifts, sand-dunes, and recent alluvia, all find adequate expression on the maps. Especial care, too, seems to have

been bestowed upon the eruptive rocks which form so important and interesting a feature of Colorado geology. The more characteristic varieties are represented by distinct shades of crimson or orange, and they have been mapped in such a way as to convey at a glance, and even without the aid of sections, a tolerably clear notion of the volcanic phenomena of the region. On the one hand we see the great lava-sheets capping the mesas and spreading far over the plateaux, on the other we notice the great centres of volcanic activity, with their abundant flows, dykes, and breccias.

Two sheets of sections, drawn across all the more interesting and important portions of the geology, complete the vast fund of information given by the maps; while, that nothing may be wanting to enable readers to realise what has been done by the Survey, and the conditions under which it has been accomplished, two large sheets of sketches are given, which most vividly represent the forms of the mountains, plateaux, mesas, and river-channels, as seen from various commanding heights.

Dr. Hayden, with whose personal supervision this great work has been accomplished, has increased tenfold the obligations under which he has laid geologists all over the world for the number and value of his contributions to geology. He now furnishes us with new light whereby to read his former researches and those of his able colleagues. May we venture to hope that he may find leisure to confer yet one further benefit before the progress of his Survey plunges him into a new whirl of work? If he could be prevailed upon to sketch out a plan for digesting the materials of his published Annual Reports, he could doubtless find among his staff some competent writer who, under his guidance, could produce a well-arranged systematic guide-book or text-book to complete the value of the work of his Survey. Such a book of reference as would give a reader who has never had access to the Annual Reports a clear and comprehensive view of Colorado geology, would be of very great service.

These remarks may be fitly closed with an expression of the warmest admiration of the liberal spirit in which the United States Government has conducted these Surveys of the Territories and has published their results. This costly atlas has been distributed gratuitously all over Europe. That this is a wise policy cannot be doubted. Whether actuated or not by a desire to diffuse scientific information, the authorities at Washington do well to make as widely known as possible the geological structure and economic resources of their country. They cast their bread upon the waters, and the harvest comes to them in the form of eager, active emigrants from all parts of Europe.

ARCH. GEIKIE

OUR BOOK SHELF

Forest Flora of British Burma. By S. Kurz, Curator of the Herbarium, Royal Botanical Gardens, Calcutta. (Calcutta: Office of the Superintendent of Government Printing, 1877.)

BY the completion of the work whose title is given above, we have the third valuable contribution to a knowledge of the rich vegetation of our Indian forests. In all three works, namely, Col. Beddome's "Flora Sylvatica of Southern India," Brandis's and Stewart's "Forest Flora of North-West and Central India," and the book now before us, there is much in common, and the plans of the two latter are very similar. There is, however, one great difference between Beddome's and Brandis's Floras and the present issue; while the first two are most profusely illustrated, the work under consideration is entirely without plates. This, perhaps, is not to be regretted considering that the work in its present form constitutes two good-sized volumes; and further than this, Indian plants have of late been very well represented, notably in the two forest floras just referred to. Another distinction, and perhaps one more affecting foresters generally, for whose benefit these floras are ostensibly prepared, is the meagre information regarding the uses of the plants mentioned. Mr. Kurz excuses himself for reducing this portion of his work to a minimum, and refers to Brandis's "Forest Flora" for information on this head. We regret that Mr. Kurz did not see his way to greater condensation in his descriptions, and, if need be, the use of smaller type, so as to reduce the bulk of the book. At the same time its efficiency would have been much increased had he followed Dr. Brandis in giving extended notes as to the uses, for to no similar work can we point with so much satisfaction in this respect as to that of Dr. Brandis.

Regarding the nomenclature of genera and species, it is a pity that some kind of uniformity should not prevail amongst the different authors. Many forest officers would, to say the least, be somewhat confused as to the use of a proper name when he finds in two books published by authority and appearing within a year or two of each other a different generic distinction for the same plant; thus Brandis keeps up the rubiaceous genus *Adina*, and figures *A. cordifolia* of Hook. fil. and Benth., placing *Nauclea cordifolia*, Roxb., as a synonym. Kurz, on the contrary, retains *Nauclea* as a genus, sinking under it *Adina cordifolia*, which is spelt *Andina*, and attributed to Roxb. On this subject of nomenclature, however, Mr. Kurz says: "I confess myself an admirer of, and adherent to, the botanical laws as laid down by the International Botanical Congress at Paris in the year 1867, and published by Prof. Alph. de Candolle. These are translated into nearly all modern languages, and are now generally adopted in Europe, except at Kew. However, I have deviated in several cases in favour of Hooker's 'Indian Flora,' or kept up old-established names, not because I assent to such irregularities, but simply because I thought it not fair that I, a German, should introduce my individual convictions into a practical work written solely for the use of English people."

Notwithstanding the remarks which we have been obliged to make, Mr. Kurz's Flora is one of very great value, and, taken in conjunction with those we have before referred to, forms a pretty complete forest flora of British India. We are reminded by the passing of this work through our hands of the loss Indian botany has sustained by the lamented death of its author.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

American Storm Warnings

THE author of the papers on the American Storm Warnings (NATURE, vol. xviii. pp. 4, 31, 61) seems well acquainted with the storms and storm-warnings of America, and at least with some of the results arrived at in Europe, and if he had confined himself to what he really knew, and to the description of the means

which are used by the *Herald* Office (with which Mr. Collins seems to be connected) to issue storm-warnings from the United States to Europe, no objection could be made against him. But Mr. Collins is more ambitious, and makes some assertions which run against the most authenticated facts known to meteorology, and others which may be true, but ought yet to be proved, while Mr. Collins, without any proof whatever, seems to consider them quite well established.

I must first object to the absence of distinction between the seasons, which is so important a feature in storms, especially in lower latitudes. Mr. Collins seems not to know that the West India hurricanes and other destructive tropical storms are frequent only at certain seasons. This is quite enough to dispose of the author's assertion "that the conditions which combine to develop nearly all areas of low pressure are of equatorial origin." The most violent storms of Europe and the United States happen in the colder months of the year, when there are no storms in the tropical belt north of the equator (very few exceptions are known); besides the use of the word "equatorial" must be objected to as, so far as I know, no cyclone has ever originated between 5° N.L. and 5° S.L., at least,[1] so that we may call the storms of the West Indies, the South Indian Ocean, about the Mascarenes, of the Bay of Bengal, &c., *tropical storms*—because they certainly originate in the tropical belt—but certainly not equatorial. So far as Europe is concerned, there are some few cases in which West India hurricanes have reached it, but this is confined to the months of July to October. At the same time of the year it is not impossible that cyclones originating in the tropical belt of the Pacific may strike the Pacific coast of the United States. As to the storms mentioned by Mr. Collins, which strike the west coast of Mexico, pass over the plateau, and thence into Southern Texas, I very much doubt their existence. In any case no storm of this kind has ever been followed on this route, and so Mr. Collins ought to be rather careful in speaking of them. So far as I know, from books published about Mexico, and from personal information, no storms are experienced on the Mexican plateau.

The same absolute want of facts and general improbability can be urged against the storms which Mr. Collins takes from the Asiatic continent to the Pacific and thence to the American continent. Here the distinction of the seasons is especially necessary, as all Eastern Asia is under the influence of monsoons or periodical winds.[2] In winter, when pressure is so enormously high in the interior of Eastern Siberia,[3] and the winds are north-west and north on the coast, that is, bring the cold dry air of the interior towards the Pacific Ocean, these conditions are favourable neither to local depressions nor to the propagation of European storms, which generally die out in Eastern Russia or Western Siberia. In summer the pressure is low in the interior of Asia, and air is constantly drawn from the Pacific Ocean to supply the deficiency towards the end of the rainy season or summer monsoon—in August to October is the time of the typhoons, that is, of the cyclones of the China Seas; but they do not originate on the Asiatic continent, and only strike it on a very limited area, that is, the coast of Southern China. These typhoons may perhaps reach California, as the West India hurricanes reach Europe, but it is not yet proved that this has ever been the case.

I admit that in autumn, that is, September and October, storms may perhaps pass from the Asiatic continent to the Pacific, and thence to America; but in latitudes far to the north of those visited by the typhoons. At Yakutsk, in North-East Siberia, the prevailing winds of that season are west and south-west, the amount of cloud great, and rains frequent, if not abundant, while the temperature is generally above freezing-point to the middle of October. I consider it possible that Atlantic (European) storms may, at this season, travel over the whole of Northern Siberia and reach the Pacific. In winter this is impossible, on account of the low temperature and high pressure then existing in Siberia.

I resume a few facts either well authenticated or very probable about storm-centres (cyclones) of the northern hemisphere.

1. By far the most of them originate in the middle latitudes (35°–65° N.) in Europe, North America, the Atlantic, and Pacific. As to the three first-named regions it is abundantly proved by the observations we have already. As to the Pacific, we want the direct proof, because observations are too few. But nobody will doubt that, in conditions of climate so analogous to those of the Atlantic cyclones do also originate.

2. Cyclones are of much rarer occurrence in Asia, except the great summer depression, which is of a different nature, and remains the whole summer over the dryest parts of the continent.

3. Tropical cyclones are confined to a few months of the year, and even these seldom reach the latitudes north of 35° N.

Lastly, a few words about Mr. Bennett's storm-warnings. I do not doubt that some storms may reach Europe from America. But it is not at all certain that every storm that has passed from the eastern coast of America should reach Europe. This is the first difficulty in storm-warnings from America. The other is, that neither the path the storm will take nor its rate of progress can be known with certainty. Every one who has examined European and American synoptical maps will have noticed how different the paths of the centres are. So long as the storm can be followed on land, by means of numerous stations, a great approximation to certainty in predicting it is possible, as the durations are caused by certain pre-existing states of pressure, temperature, humidity, &c. But how is this to be done on the ocean?

Meteorologists of great ability, especially Prof. Buys Ballot, have often advocated telegraph lines to the Azores and Iceland, so that these islands might serve as advanced guards to predict storms in Europe. At such a distance as they are from our continent they certainly could serve this purpose, as is clearly shown by the French Atlas Météorologique and Hoffmeyer's synoptical maps. As to American predictions for Europe, I must confess that most European meteorologists are very doubtful about it. It is to be noticed also that, as storms are very frequent in western Europe, and as the rate of progress of storm-centres over the Atlantic is not accurately known, there may be a seeming success in American predictions which the facts, when accurately known, would not justify.

This is not meant to cast a shade on the spirit of enterprise of Mr. Bennett in organising the *Herald* weather predictions. The observations thus collected, or saved from oblivion, will certainly be useful, even if it be proved that storm-warnings from America are not reliable. A. WOEIKOF

St. Petersburg

[1] It would be too long to state why there are no equatorial cyclones. I would advise Mr. Collins to consult "Études sur les Mouvements de l'Atmosphère," by Guldberg and Mohn.

[2] See "Winds of the Globe," by Coffin.—Smithsonian Contrib. vol. xx.

A White Grouse

WHEN shooting, yesterday, on the moors near Dunrobin, I fired at an ordinary grouse and killed it; just as it fell, another bird rose that seemed to be a ptarmigan, from the complete whiteness of its plumage; a third bird then rose, and was shot. The three were picked up not far from each other, and were all very fine birds. It seemed strange that a ptarmigan should be so low; we were not very high above the sea, and far below the elevation affected by these birds. On examining it, it proved to be a very fine grouse, snowy white, with a few dark feathers in the tail and wings. It was not an albino; I think the eyes were dark. It is a very beautiful bird, has been sent off to Inverness to be stuffed, and will be preserved in the Dunrobin Museum.

No one here had seen a specimen of the white grouse before, and it excited considerable interest. No doubt it is only an accident, and its progeny, if it had any, would have been the ordinary grouse.

It may be less rare than I suppose, but you may deem its occurrence worthy notice in NATURE. J. FAYRER

Dunrobin Castle, Sutherland, September 8

Brehm's "Thierleben"

IN last week's NATURE you have copied a drawing, "cobra charming," from Brehm's "Thierleben," presumably for its excellence. Permit me, however, to point out a most serious defect in its truthfulness—the relative proportions of the snakes to the charmers.

Take the youth blowing the horn to be 4 feet 6 inches in height (he could not be much less), the hoods of the cobras must be 8 to 9 inches across. Now I will venture to say that a hood of $4\frac{1}{2}$ inches across has never yet been measured, in a live specimen at least.

I cannot now lay my hands on a cobra skin I have, and give

exact measurements, which I am sorry for, as the cobra in question measured 6 feet 3 inches in length, a size Col. R. Beddome—no mean authority—assured me is seldom or never surpassed.

In a work such as Dr. Brehm's, exaggerations in illustrations should be as carefully avoided as misstatements in letterpress. A Natural History that depicted horses the size of elephants would be scoffed at, yet, strange to say, equally glaring absurdities, such as "cobra charming," frequently pass muster.

Bath, September 10 E. H. PRINGLE

The Sea-Serpent Explained

IF you have space for the following, it is so confirmatory of Dr. Drew's experience of an opera-glass dispelling "fond deceits" concerning a sea-serpent, that it may be worth recording.

One morning in October, 1869, I was standing amid a small group of passengers on the deck of the ill-fated P. and O. ss. *Rangoon*, then steaming up the Straits of Malacca to Singapore. We were just within sight of the coast of Malacca, and quite out of sight, so far as I remember, of Sumatra. One of the party suddenly pointed out an object on the port bow, perhaps half a mile off, and drew from us the simultaneous exclamation of "The sea-serpent!" And there it was, to the naked eye, a genuine serpent, speeding through the sea, with its head raised on a slender curved neck, now almost buried in the water, and anon reared just above its surface. There was the mane, and there were the well-known undulating coils stretching yards behind.

But for an opera-glass, probably all our party on board the *Rangoon* would have been personal witnesses to the existence of a great sea-serpent, but, alas for romance! one glance through the lenses and the reptile was resolved into a bamboo, root upwards, anchored in some manner to the bottom—a "snag," in fact. Swayed up and down by the rapid current, a series of waves undulated beyond it, bearing on their crests dark-coloured weeds or grass that had been caught by the bamboo stem.

Ignorance of the shallowness of the straits so far from land, and of the swiftness of the current, no doubt led us to our first hasty conclusion, but the story, with Dr. Drew's, shows how prone the human mind is to accept the marvellous, and how careful we should be in forming judgments even on the evidence of our senses. E. H. PRINGLE

Bath, September 10

DR. DREW'S letter in NATURE, vol. xviii. p. 489, recalls to my mind a similar phenomenon witnessed by myself and a friend on August 3, while crossing from Grimsby to Rotterdam. It was towards evening, when, looking ahead, we saw, about a mile distant, what appeared to be a long, low, black hull, without masts or funnel, moving through the water at enormous speed. After a minute or two it undulated and rose from the surface, and we saw that it was a flight of birds.

The deception was so complete that I can well believe that at least *many* of the stories of the sea-serpent have so originated, though I doubt whether *all* can be explained in this manner.

Grammar School, Bradford, September 7 C. BIRD

THE communication of Dr. Joseph Drew in your issue of yesterday regarding the serpentine appearance of a flock of shags in the English Channel is extremely interesting even as a mere fact regarding the habits of these birds. Will you kindly permit me, however, to point out that Dr. Drew's statement cannot be regarded as explanatory of the sea-serpent's personality? At the most the incident only explains one of a number of *serpentine appearances* of which porpoises and sunfishes swimming in line, pieces of wood with trains of sea-weed, &c., are also good examples. There have been placed on record numerous incidents of serpentine forms having been closely inspected (as in the well-known case of the *Dædalus*, or later still of H.M.S. *Osborne*) where the hypothesis of the serpentine appearances assumed by flocks of birds or fishes could not be held as explanatory in any sense. It is with the view of showing that the exact personality of the "sea-serpent" cannot be accounted for by such an incident as Dr. Drew relates, that I venture to pen these remarks; and as a firm believer from the standpoint of zoology that the large development of the marine ophidians of warm seas offers the true explanation of the "sea-serpent" mystery, I would also ask your readers to distinguish carefully between cases in which serpentine appearances have been assumed by ordinary animals, and those in which *one* animal form has presented itself in the guise of the "great unknown." I am far from contending that a sea-snake developed in the ratio of a giant "cuttle-fish," presents the only solution of this interesting problem. A long tape-fish, or even a basking shark of huge dimensions, might do duty in the eyes of non-zoological observers for a "sea-serpent." The following cutting from the *Scotsman* of September 6, indeed, seems explicable only on the tape-fish theory which I have advocated with the persistence of firm belief within the past few years. At the same time zoologists cannot but feel indebted to Dr. Drew, and to those who, like that gentleman, note unwonted appearances in ordinary animal life, and communicate such incidents to your columns. ANDREW WILSON

Edinburgh School of Medicine, September 6

The following is the extract alluded to:—

"A BABY SEA-SERPENT.—From Van Diemen's Land comes news of the capture of a queer fish. It is fourteen feet long, fifteen inches deep from the neck to the belly, tapering two inches to the tail, and eight inches in diameter in the thickest place. There are no scales, but the skin is like polished silver, with eighteen dark lines and rows of spots running from the head to the tail each side. There is a mane on the neck twenty inches long, and continues from the head to the tail; small head, no teeth, protrusive mouth, capable of being extended four inches like a sucker; eyes flat about the size of a half-crown, and like silver, with black pupils. There are two feelers under the chin, thirty-two inches long. The fish was alive when captured."

Alpine Flowers

IN the Alps I have found some instances of *different forms of flowers in plants of the same species*, which, as far as I know, have been hitherto undescribed, and of which, therefore, I will give a short notice here.

Geranium sylvaticum is in one locality near the Albula Pass *gynodiœcious*, with large-flowered hermaphrodite, and small-flowered female stems. *Veratrum album*, *Dryas octopetala*, and *Geum reptans*, are in all the localities where I have examined them, *androdiœcious*. *Astrantia minor* offers a quite peculiar sort of androdiœcism, some stems bearing, as in other Umbelliferæ, in the same umbel hermaphrodite flowers and male ones, other stems producing solely male flowers. *Dianthus superbus* seems at first sight to exist in three forms: (1) stems with hermaphrodite flowers, being perfectly proterandrous and producing a moderate quantity of *whitish* pollen; (2) stems with female flowers containing very conspicuous rudiments of stamens but pollenless anthers; (3) stems with pistils remaining imperfectly developed and with anthers containing abundance of a *brown* powder. At first sight I thought their flowers to be male, and the brown powder to be pollen grains, but under the microscope the latter proved to consist of grains, the diameter of which is only about one-eighth of that of the pollen grains of the hermaphrodite flowers. I suppose, therefore, these grains to be the spores of some species of fungus, and *Dianthus superbus* to be *gynodiœcious*.

Berninahaus, August 29 HERMANN MÜLLER

The Microphone

WHILE studying the relation between the battery power and the sounds heard through the microphone, I found, when the latter was included in the circuit *between* two pairs of elements, that the sound first amplified by the microphone underwent further amplification by the action of the second pair of elements, and when heard through the telephone the volume of sound was considerably augmented. This new fact may perhaps open up a fresh avenue of research and lead to further development of Prof. Hughes' beautiful discovery.

Hull THOMAS ROWNEY

A Meteor

WHILE directing a small telescope towards Jupiter, at 9.35 P.M. on the 2nd inst., my attention was attracted by the bright light of what proved to be a large meteor, falling towards the south-western horizon. Its apparent size was two or three times that

of Jupiter, its colour being green (very similar to that of burning silver), suddenly changing to a dull red on falling to pieces at the end of its course.

The meteor appeared at about R.A. 18h. 10m., Decl. S. 10°, and travelled slowly till it broke up in R.A. 17h. 0m., Decl. S. 16° (or nearly coinciding with the star η *Ophiuchi*), being visible for about three seconds. SYDNEY EVERSHED

Wonersh, Guildford, September 4

OUR ASTRONOMICAL COLUMN

THE INTRA-MERCURIAL PLANET.—The correction applied by Prof. Watson to his first position of the supposed intra-Mercurial planet from more complete reduction of his observation brings the object somewhat nearer to the ecliptic, the longitude being 124° 46′ and the latitude 0° 51′ S., at 10h. 24m. 49s. G.M.T. on July 29. Close and continued search along the ecliptic with large refractors, provided with long "dew-caps" blackened inside, for 10° or 12° on each side of the sun, may now afford the best chance of recovering the planet previous to the next total solar eclipse, or probably until the eclipse in May, 1882; for it will be seen that in the eclipse of January, 1880, the duration of totality is short, and, which is of still more consequence, the central line runs mainly amongst the Pacific Islands without touching any, where observations would be likely to be very practicable. With respect to the precautions that may be usefully adopted in a search for the planet, the reader may consult the remarks of Prof. Julius Schmidt in *Astron. Nach.*, 878, bearing upon his daylight observations of the great comet of Klinkerfues in 1853.

VARIABLE STARS.—Prof. Schmidt notes the variability of the star Lalande 46090, rated 6m. in the catalogues of Argelander and Heis, but which was invisible without the telescope on July 9 and 10, 1878. It is 7m. in Bessel, and only 8·9 in Lamont. The position for 1880 is in R.A. 23h. 26m. 12s., N.P.D. 101° 39′·6.

The Athens observations, last May and June, establish a material increase in the period of the well-known variable δ Libræ. The error of Schönfeld's ephemeris in May, 1877, was—32m.; in the present year it was—48m., from the naked-eye observations, considered preferable to those made with the comet-seeker. χ Cygni was at a maximum (hardly 5m.) on March 14, 1878, 408·6 days having elapsed since the preceding maximum. Prof. Schmidt refers to a star in the nebula of Orion, No. 822, of Bond, which exhibited marked change of brightness in April last, having been seen as faint as 12 8 and as bright as 9·7. This star follows θ, 34·3s., and is south of it 5″·1. In previous years he had not noticed any sensible difference between No. 822 and No. 784, which precedes 8·5s. and 0″·3 to the north.

Mr. Tebbutt writes from Windsor, N.S.W., with recence to our notice of his newly-discovered variable in Ara, that in his communication to the *Astron. Nach.* the field of view should have been given as about half, instead of three-fourths of a degree. Although Brisbane 6,142, is still visible as a star of the eighth magnitude, 6,183 of the same catalogue cannot now be found; but an error of two minutes in the observed R.A. will identify it with 6,196, exactly on the same declination.—Prof. Bickerton, of Canterbury, N.Z., sends us an outline of a lecture delivered by him at the Philosophical Institute of this place, on the explanation of the phenomena of variable stars. Amateurs in such latitudes may do excellent service, with comparatively little expense of time, and with very small optical means, in furthering our knowledge of the variable stars of the southern heavens, providing themselves for the present with Behrmann's Atlas, the magnitudes in which are recorded from recent observations; while at no distant time it may be expected the charts of the Cordoba *Uranometria*, prepared under much greater advantages, will be available to them. The popular atlases are useless in such investigation. We hope the result of attention being directed to subjects of this nature at the Antipodes may be to greatly increase the number of observers in departments of practical astronomy, peculiarly within the scope of the amateur, as, compared with what is now to be effected with limited means and appliances in the northern hemisphere, a promising field is open to them.

SWIFT'S COMET OF JULY 7.—Elements of the comet discovered by Mr. Lewis Swift, of Rochester, N.Y., on the morning of July 7, have been calculated by Dr. Holetschek, from observations to July 23, made at Clinton by Prof. Peters; they do not resemble those of any comet previously computed. The failure to observe this object in Europe, though it was closely sought after at several observatories, appears to have arisen from an error in the telegram, which stated its motion to be slow, whereas it was pretty rapid towards the south-west horizon. It might have been well observed during June, the position at the beginning of the month being in the vicinity of ψ Cygni, and on June 21 just south of 13 Lyræ. The elements are in *Astron. Nach.*, No. 2,213.

THE SATURNIAN SATELLITE MIMAS.—The series of observations of the satellites of Saturn, in 1877, made with the great refractor at Washington, includes but few of the closest satellite *Mimas*, which, indeed, has not been frequently observed of late years. A combination of the later Washington measures, with observations made by Mr. Lassell in 1847, and a few intermediate ones, indicates, on the assumption of a circular orbit in the plane of the ring, a period of 22h. 37m. 6·82s.; but there appear grounds for suspecting a very slow increase in the length of the period. Mädler, from his reduction of the observations of Sir W. Herschel, considered a very sensible eccentricity was shown by them, which more recent observations support. In the case of *Hyperion*, the perturbations as indicated by the measures must be very large, but we believe Mr. Marth has found the same result some time since from his investigations on the theory of the satellites, the chief disturber being, of course, *Titan*.

GEOGRAPHICAL NOTES

WE have received three new maps of Cyprus. The first, to which we have already briefly referred, is by the well-known German geographer, Dr. Kiepert, and is a valuable original compilation based upon the English Admiralty chart, but containing many more names of villages, &c., than any other modern map. A noticeable point of this map is the hill-work, which has been very artistically rendered. Stanford's Cyprus is also an original work, with some useful features not found in Kiepert's. The Kaimakamliks and Kazas are all distinctly bounded and named, and although there are not so many names as in Kiepert's map, yet those that find a place appear to have been judiciously selected. The spaces around the map are utilised by the insertion of supplementary maps presenting the agricultural and geological conditions, a section showing the interdependence of these conditions and plans of the chief coast towns and roadsteads. Wyld's Cyprus is on exactly the same scale as Mas Latrie and the Admiralty chart, and appears to be a combination of these two. We notice in one or two places where the positions of villages do not agree in these two authorities, that both positions are inserted on Wyld's map, as though there were two places of the same name. The hills on this map are inferior to Kiepert's; there are few English lithographers that can equal the German in this art. This map, like Stanford's, introduces agricultural and geological insets, and plans of the chief roadsteads and coast towns. We need not

be surprised at the alleged unhealthiness of Cyprus, when Mr. Wyld tells us that the average temperature in February is 52·8° *Centigrade*, and that of July and August 82° of the same scale!

LIEUT. KITCHENER, R.E., has handed over to the Committee of the Palestine Exploration Fund the whole of the memoirs, special plans, and lists connected with the great map of Western Palestine. These materials, now in the hands of the Committee, consist of a map in twenty-six sheets, on the scale of one inch to a mile; a map in three sheets, on the scale of three-eighths of the large map; and an immense collection of memoirs from the note-books of Lieut. Conder and himself. The Committee have already taken steps for the publication of the maps, and will at once proceed to consider that of the memoirs, a part of the work as important as the map. Lieut. Kitchener exchanges the work of the Palestine Fund for the important charge of the survey of Cyprus, to which he has been appointed by the Foreign Office. He achieved in Palestine what may be called the unparalleled feat in survey work of surveying 1,000 square miles for 1,000*l.*, and in eight months.

WE learn from Washington that Capt. Tyson is expected in America with the *Florence* in which last year he made a preliminary trip, with the view of establishing a polar colony at Lady Franklin's Sound. The scheme, which has been devised by Capt. Howgate, of the Signal Service, has not been given up, but postponed for one year, Congress having terminated its session without any resolution having been taken on the necessary grant of credit. It will be proposed again when the Congress meets in 1879, and the report drawn up this year by the special commission will receive an additional force from observations taken by Capt. Tyson and his able scientific staff.

THE *Geographical Magazine* for September describes the equipment of two expeditions from the United States for the survey of the Amazon. One of these is in the *Enterprise*, under Commander Selfridge, of the U.S. Navy, which will survey the river as far as Manaos, and the Madeira as far as San Antonio, the point of departure of the line of railway around the Falls of Madeira. The other expedition is sent out by Messrs. Mackie and Scott, of Philadelphia, its object being to arrange a route by way of the large rivers which connect Bolivia and Brazil, over which trade can be carried on. As a preliminary measure a surveying party will go to Bolivia to study the country, and will be accompanied by a naturalist, Mr. Ernest Morris, who has already done good work on the Lower Amazon.

THE just published June number of the *Bulletin* of the French Geographical Society contains M. de Ujfalvy's account of his official journey to Zarafshan, Ferganah, and Kuldja, which contains a good many original ethnological observations. Dr. Hamy has a paper on Manoel Godinho de Eredia, the Portuguese whom Mr. Major and others had accepted as the earliest discoverer of Australia; fuller evidence, however, convinced Mr. Major that Godinho had no claim to this honour, and Dr. Hamy endeavours to show what were the real services rendered by this "Descobrider" to geography. The number contains the letter from Savorgnan De Brazza, describing his journey on the Ogové, to which we alluded some time since.

FROM the *Bollettino* of the Italian Geographical Society we learn that Romola Gessi had been furnished with a formidable equipment for the exploration of the Sobat, by Gordon Pasha, who, at the last moment, was compelled to stop the expedition, on account of a formidable rebellion in Darfur.

M. PAUL SOLEILLET, who, it will be remembered, was to cross Africa from Senegambia to Algeria, reached Kuniakaro on June 23 by way of Bakel. This was 1,250 kilometres beyond St. Louis, and thitherto M. Soleillet had few difficulties. After Kuniakaro, however, the real work of the expedition will commence, and not a few dangers will have to be faced. His next point was Yamina, a small town on the banks of the Joliba, about 50 kilometres from Segou.

LETTERS have been received in Holland from the members of the Dutch North Polar Expedition, and their contents are said to be highly interesting. The expedition, after leaving Bergen, had proceeded to Jan Mayen, where they arrived on May 9. On June 27 they reached Amsterdam Island, where a simple monument was erected in memory of the Dutch sailors buried there. The expedition then visited the other principal points of Spitzbergen, and eventually sailed for Vardö, on the north coast of Norway. It was then their intention to cross the Barentz Sea in order to reach Novaya Zemlya in the middle of August. The letters state further that numerous scientific observations have been made.

DR. GERHARD ROHLFS, after finding that his efforts to form a large society with a view of organising an exploring expedition to Africa upon a grand scale, have not met with the success he anticipated, has now resolved to start alone as on former occasions.

AT the meeting of the French Geographical Societies in Paris a number of resolutions were adopted, bearing principally on the teaching of geography and topography in the public schools, the creation of regional geographical museums and congresses, the means of multiplying the number of geographical societies, and fostering intercourse between members of the several European societies. It was decided that all the members of the different French and Algerian societies should have the right to be admitted to each others meetings. It was proposed to advise foreign societies to do the same, and to adopt an universal geographical society's ticket. The next national geographical exhibition will take place at Montpellier in 1879, on the occasion of the meeting of the French Association. A conference of all French societies will also be held at the same time.

THE gold medal for English maps, charts, &c., at the Paris Exhibition, has been awarded to Mr. Stanford.

BREWING IN JAPAN

AT the present time, when the history of the origin and development of the lower forms of life is occupying a great deal of attention, any facts which increase our knowledge of the growth of such bodies should be welcomed. In our breweries the growth of the yeast-ferment is tolerably well understood, or, at least, has been well observed and described. Under ordinary conditions the yeast-fungus exists only in the aquatic form, as it may be termed; and only under special circumstances, and with considerable difficulty in preventing putrefaction, is it enabled to produce spores. The internal substance of the cell becomes differentiated; granulations form and collect round certain points, and these ultimately become invested with a membrane, upon which the spores are ripe. The production of spores is thus unattended with the formation of a mycelium, or, if formed, it is so minute as to have been overlooked. This, however, is not a normal process of reproduction: the principal one, and indeed under the usual conditions, the only mode, is by budding.

Those living in Japan, however, have the opportunity of seeing a mode of fermentation which differs in many particulars from that employed in Europe. The subject is now under investigation, and at present I am not able to explain accurately what takes place; but as the process followed is interesting from its novelty, as it appears to consist in the previous practical use of a discovery

made by De Bary, and afterwards confirmed by Rees and by Fitz, that alcoholic fermentation can be effected by the growth of a species of *Mucor*, I am induced to give an account of a visit made, in company with some scientific friends, to the saké breweries situated about thirty miles away from Tokiô, the capital of Japan.

Saké is the general name given to the alcoholic liquid prepared by the fermentation of rice. There are many varieties of it prepared in different parts of Japan, each receiving some special name, either derived from the district in which it is prepared, or from some fancy of the manufacturer. It is a clear liquid, of a colour varying from the palest yellow to that of the darkest sherry, and containing from twelve to fifteen per cent. by weight of alcohol. There are some special kinds which contain much less alcohol—from four to five per cent—but they do not form the usual drink of the Japanese. It is almost always served hot, being placed in porcelain bottles, which are immersed in hot water and left there until the whole has attained the proper temperature.

This liquid is prepared on the large scale only in certain parts of the country, the most famous district being that near Ôzaka, one of the Treaty Ports. It is, however, often prepared on the small scale in private houses. The winter is the only season during which brewing operations are conducted, but this is not because the fermentation temperature is to be kept low as in the Bavarian method, but, I believe, in order to prevent the action becoming too tumultuous, for the temperature of fermentation is, in reality, even higher than that adopted in England. But, from the fact that the largest breweries are situated nearly 400 miles from Tôkiô, and the operations being carried on during a period when the University session is at its height, I have been compelled to confine my inquiries to the smaller breweries at Hachiôji, near this city.

The main room consists of a large wooden building about 120 feet long by 50 feet broad, and 25 to 30 feet high, running along the middle of which, in the direction of its length, is a platform about 12 feet from the ground, upon which some of the preliminary operations are carried out. Upon this a number of wooden tubs are placed, which serve for the preparation of the ferment, an operation which requires to be repeated several times during the brewing season. On the ground, ranged along the two long sides of the building are large tuns used for the storing of the saké when made, and some of which are also used for the actual processes of fermentation.

The brewing commences with the preparation of the ferment. For this purpose at the end of the previous brewing season a quantity of a green mould is produced upon rice by exposing steamed rice mixed with a certain proportion of the ash of some tree, and over which the spores of this fungus have been scattered in a well-closed chamber, which I may term the "fungus-chamber." This is a small room about 7 ft. high by 6 ft. broad, and 8 ft. long, well lined and covered with straw and matting, so that its high temperature may be kept up for a considerable time. In this chamber the rice and spores are left for about ten days, the atmosphere being kept quite moist by the vapour given off from the steamed rice, and at the end of that time the grains are found to be covered with a green fungus full of spores, and apparently the same kind as is found growing upon putrefying organic substances. The temperature of the chamber when examined was 25° C., that of the external atmosphere being 13° C. This product is called, in Japanese, *tane* or seed.

When prepared at the end of the season it is preserved until the next by being placed in bags, and inclosed in wooden boxes between layers of a mixture of equal parts of lime and wood-ashes.

When it is required to commence operations, a similar method is adopted to that just described, that is, a quantity of steamed rice is placed on wooden trays in the "fungus-chamber," but not mixed with any wood-ashes, and then *tăné* (spores) is scattered over it, and the chamber kept closed for a period varying from two to four days. At the end of this time the rice-grains are found to be covered with large quantities of fine hair-like threads, the mycelium of the fungus added. In this state it is called "kōji."

If this were left for a longer period in the fungus-chamber, it would produce spores, and the brewer calls it "the friend of tane," but in order to carry on the development of the mycelium most vigorously, it is necessary to use wood-ash in addition, which thus seems to act as a fertiliser.

Having thus obtained the "kōji," or mycelium, the brewer uses it for effecting the preparation of his yeast. For this purpose he mixes steamed rice with 30 per cent. of its weight of "kōji" and a sufficient quantity of water to make a thick mud, in small shallow wooden tubs, which are kept on the platform previously mentioned. In these it is frequently stirred and rubbed round with wooden tools, during a period of about ten days, in the course of which the grains of rice appear to be broken down, and the whole assumes a much thinner consistence, while at the same time the liquor becomes decidedly sweet. This is a change which is anything but clear; it would seem that it is connected with the development of an organism derived from the "kōji;" as on the small scale, I have noticed the production of minute cells, apparently budding, but whether they have any connection with the air-fungus, the mycelium of which covers the rice in "kōji;" or whether they have been developed from germs accidentally present in the "kōji," I am not able to say, though I hope that further experiments will make this point clear.

After the end of the ten days this product is mixed with fresh-steamed rice, water, and "kōji," and introduced into larger wooden vessels, in which the mixture is heated by means of closed wooden tubs, containing hot water, and in order to prevent too rapid radiation, the whole is covered with matting. The hot-water tubs are replaced day by day, so that the temperature is kept up for a period varying from eight to thirteen days. The average temperature seems to be about 35° C. (95° F.). During this time there is a continuous development of gas, and a scum gradually forms upon the surface until it has a thickness of a little more than one inch, and, when examined under the microscope, presents the usual appearance of brewer's ferment—saccharomyces. At the end of this stage, if the operation has been well conducted, five tastes are to be distinguished: sweet, bitter, astringent, alcoholic, and sour; but of these five, all of which are quite distinct, the bitter, astringent, and sour tastes are most marked. The product of this operation is called "moto," which means "source" or "origin," referring to the fact that it is from this ferment that the saké is subsequently formed. All the previous part of the brewing process has thus had for its object merely the preparation of the yeast, but it is certainly the most interesting, from the obscurity which surrounds it.

The actual fermentation is divided into three stages, called respectively *beginning*, *middle*, and *end*, the proportions of steamed rice and ferment varying slightly in each stage, but giving a final result of 100 parts of steamed rice to 30 parts of ferment. This mixture, together with the proper quantity of water, is placed in one of the large tuns before mentioned, and allowed to remain for about fifteen days in all, during which time fermentation actively proceeds, and the liquid becomes strongly alcoholic, at the end of which time it is drawn off from the grains of rice which have subsided, and introduced into other tuns, where it is allowed to remain to permit the remainder of the rice to be separated. The residue is placed in bags and subjected to pressure in a

lever press, the clear liquid which is expressed being added to that which has been clarified. It is now placed in boilers and heated up to about 60° C., after which it is kept in the store vats, carefully sealed up.

The residue left in the press is subjected to a process of distillation in a current of steam, by which a spirit containing about 42 per cent. of alcohol is obtained.

The saké in the store vats contains about 15 per cent. of alcohol, and this fact shows that the fermentation is different to that effected by the *Mucor racemosus*, as described by Fitz. In his experiments he found that the presence of $4\frac{1}{2}$ to $5\frac{1}{2}$ per cent. of alcohol killed the ferment, whilst in the process above described, we find the ferment acting in such a way as to produce 15 per cent. There is, however, nothing improbable in the supposition that different species may possess different degrees of sensitiveness to alcohol, and that the species used here may be less easily affected than the one employed by Fitz.

There are, however, many points about the process which are obscure, and about which I cannot say anything at present, but further experiment will, it is hoped, throw light upon the obscurity now enveloping the subject. The above account has been given in the hope that it may prove of some interest to those engaged in the study of fermentation, and that it may lead to a more extended examination of the action of various species of fungus upon amylaceous substances.

R. W. ATKINSON

University of Tokio, Japan

THE ORIGIN AND DISTRIBUTION OF ORGANIC COLOUR

COLOUR, throughout the realms of organic nature, is a factor hitherto held to be the most capricious in its distribution and the least amenable to any finite law. So uncertain and variable indeed are its manifestations that its claims for the purposes even of specific diagnosis have long since been ignored by the comparative anatomist. Nevertheless, when examined more attentively, an amount of evidence may be adduced sufficient to warrant further inquiry as to whether there is not existent beneath the superficial stratum of apparent disorder, a harmonious under-current indicative of a derivation in the abstract from one of nature's simplest physical laws, namely, that of polarisation.

Directing brief attention first to the subject of colour as distributed among the animal world, it will at once be recognised that, with few exceptions, it is only amongst the classes lower in the scale than the mammalia that this element either attains or retains its full exuberance. Even within such limits it will be further found that the beautiful and recently-discovered law of natural selection, for the purposes of concealment or protection, has in many instances so influenced and subordinated all pre-existing characters as to have entirely masked or eliminated them. The lepidopterous order of the class Insecta most prominently illustrates this latter case; the brilliant and varied hues of many members of this tribe being, as has been ably demonstrated, more especially by Mr. Alfred R. Wallace, in accord either with the flowers they most frequent, the objects upon or adjacent to which they rest in repose, or, still more remarkably, mimetically identical with those of other perfectly distinct species which owe their immunity from the attacks of birds to their peculiar acrid flavour.

The types among which have been first observed those peculiar colour-characteristics now to be submitted, are more particularly associated with aquatic life, and from these latter it has been found possible to extend and institute comparisons amongst almost every terrestrial group. Reference is here made to the dominance among the animal types in question of those so-called "complementary colours" familiar to all acquainted with the working of the polariscope. Of these colours in question, the combinations red and green, and blue and yellow are the most important, and it is surprising to find how frequently these reproduce themselves in nature.

Enumerating on this occasion merely a few instances, reference may be first made to those forms in which blue with its complementary hue, yellow, are found associated. Blue, as a rule, enters but to a comparatively trifling extent into the coloration of our indigenous fish fauna, but a remarkable and very gorgeous exception is afforded by the male of the Cuckoo Wrass (*Labrus mixtus*), which in its adult condition is resplendent with equally-distributed tints of the purest azure and most brilliant orange. These same complementary hues of blue and yellow obtain again in the male of another British fish, known as the Gemmeous Dragonet (*Callionymus lyra*). A conspicuous exotic example of the same colour-combination is presented by the Tesselated Parrot Fish of Ceylon (*Scarus hariæ*), characterised by its groundwork of azure blue decorated with an hexagonal network of golden yellow. Among the invertebrate division of the animal kingdom, the class of the Crustacea affords several interesting instances of a similar combination. Two of these belonging to the Decapodous order, *Galathea strigosa* and *Scyllarus arctus*, are of considerable size, having the deep orange hue of the general surface of their carapace variegated with bands and markings of brilliant blue. The Common Lobster (*Homarus vulgaris*), again, often "sports" into a bright blue variety, variously spotted and mottled with yellow. The legs of the Common Prawn (*Pandalus annulicornis*) are also most usually decorated with alternating rings of blue and orange. The marine copepods, more especially those of tropical seas, abound with instances of the association of these same two complementary hues. The class of the Mollusca is one among which blue as a pure colour but very rarely presents itself. There are, however, two Nudibranchs (*Goniodoris cœlestis*, Desh., and *G. elegans*, Cantraine) conspicuous for their ground colour of azure, accompanied in each instance by spots or lines of yellow. The last-named and finer of these two species, attaining a length of $2\frac{1}{2}$ inches, and usually classed as a Mediterranean type, was collected by the writer on the rocky shore of the Cies Islands, Vigo Bay, in association with the dredging expedition of Mr. Marshall Hall's yacht *Norna*, during the spring of the year 1871.

Pursuing the investigation among terrestrial types, the bird tribe—although it is necessary here to cite almost entirely tropical forms—produces abundant instances of the association of the same blue and yellow tints. The large Blue and Yellow Macaw (*Ara ararauna*) of South America forms a most conspicuous illustration, and the same two complementary hues will be found coupled together among innumerable other representatives of the parrot tribe, and likewise among the toucans. The most exquisitely beautiful blue bird yet known to science, the Azure Cæreba (*Cæreba cyanea*), is not altogether deficient of the complementary tint of yellow, several feathers of this colour appearing in the wings. One of the Cassowaries (*Casuarius kaupi*, Sclater), as figured in the Zoological Society's *Proceedings* for the year 1872, is represented as having the skin of the upper and front portion of the throat coloured azure-blue, while immediately behind and adjacent to this succeeds a patch of bright yellow. A still later and highly characteristic example is likewise afforded by the newly named *Euphonia insignis* of Messrs. Sclater and Salvin, figured at Pl. lii. Fig. 1 of the third part of the same *Proceedings* for this current year. Although our indigenous avifauna produces very few species in which the colour blue occupies a prominent position, the little Blue Tomtit (*Parus cœruleus*) is an exception which at the same

time altogether conforms to that law of polarity here brought forward. Thus while the feathers on the head and back of this familiar species are of a bright cerulean blue, those of the breast and under-surface are mostly yellow. Higher than the birds it seems useless to seek for the association of the two complementary tints under notice, though singularly enough one of these, the blue, turns up where it might be least anticipated, namely, amongst certain of the baboons, or Simiadæ, whose cheeks and remarkable posterior callosities are not unfrequently coloured bright cobalt. So late as the commencement of historic times our noble ancestors are reported to have supplied what nature had denied them in this department by the adorning of their persons with the juice of woad.

Turning now to the second complementary combination, that of red and green, it will be found to be far more extensively distributed even than that just discussed, birds, reptiles, fishes, and almost every class of the invertebrate kingdom supplying an important quota in which these colours are placed in juxtaposition. From among the first-named, the parrot tribe, woodpeckers, certain pigeons (*Ptilonopus*), trogans, and humming-birds, furnish abundant examples. Among lizards may be mentioned the Indian genus *Calotes*; while the ballan and corkwing wrasses, the Connemara sucker, and even the common stickleback in its breeding-dress, illustrate familiar examples of our indigenous species of fish in which green and red constitute the two dominant hues. To this last-named list of fishes might be added innumerable exotic types. With the crustacean class green and red appears to be a scarce combination, but one marine Isopod (*Spheroma*), remarkable for the variation in colour of different individuals, supply an exceptional illustration, I having by me alive at the present moment two examples, one of which is pale green, and the other scarlet. A spider, with whose technical name I am not familiar, but which often occurs on laurel bushes, has its body apple-green, supplemented with a bright red spot in the posterior region. Aphides, whose bodies are usually green, have frequently associated with the same scarlet or crimson eyes, and the same two colours will be found to be the prevalent tints of the larvæ of many lepidopterous insects. Green and red ascidians, worms, and zoophytes might likewise be enumerated, and the same combination is further traceable down to the Protozoa, and within the precincts of that debatable ground from whence both plants and animals take common origin.

Here, indeed, the subject assumes its most interesting and important phase, it being evidently at this initial point that the key and origin of the whole attendant phenomena are to be sought. Among a number of these humble unicellular organisms, including apparently as undoubted animals the Euglenæ or Astasiæ, and as true plants the Thecomonads and Volvocinæ, it will be found that the brilliant green hue of the general cell-substance is supplemented at one point by a brilliant scarlet speck, with which, in the case of animal organisms, the properties of a visual organ have been frequently associated. Though this interpretation does not meet with general support, it is remarkable how persistent is the presence of scarlet eyes among the more minute representatives of several invertebrate classes, including Insecta, Crustacea (some of these *monocular*), Annelids, and even Echinoderms, as typified by the starfish tribe. Advancing further on the vegetable side, the complementary colours of red and green, as first foreshadowed in unicellular Phytozoa, become still more conspicuously associated. Altogether apart from the floral elements the colour red constantly accompanies the more general green cellular structure of the stems, petioles, and leaf venation of ordinary plants. One remarkable Mexican species, indeed, *Pointsettia pulcherrima*, affords an instance in which the whole foliage forming a rosette at the terminal portion of the plant is the most brilliant scarlet, while that of the lower part is simply green. *Calladiums*, *Begonias*, and many other types might be quoted, in which the same two colours are equally blended in the leaves. Among the flowerless cryptogams, again, the group of the Bryaceæ, or moss tribe, yields further analogous and corroborative data. The peculiar fimbriated structure or peristome, which upon the dehiscence of the operculum guards the aperture of the spore capsules in this group, being in the majority of instances bright scarlet or crimson. The brilliant floral elements of the phanerogamic class are not so easily subordinated to that law of polarity, which appears to have left its impress on the simpler vegetative parts. Cross-fertilisation and numerous other external conditions and surroundings have no doubt exercised their influence in this case to an extent parallel to, though not identical with, what obtains among the Lepidopterous group of the animal series. Even here, however, it is a matter of question whether red is not the colour most extensively distributed. Certain forest trees, for example, such as the larch, poplar, and hazel (female flower), form interesting exceptions among a group more usually altogether wanting in brilliant floral decoration, and in all of which instances red is the characteristic hue of the flowers they bear.

How, or in what manner, the varied colours of nature were first called into existence is a problem that yet remains to be solved. Without presuming to put forward or propose any arbitrary interpretation of this primeval derivation, the following data may be tentatively submitted. The initial term of the series, as represented amongst the lowest animals and lowest plants, and in the latter instance continued throughout the higher forms, is evidently the colour green. Associated with vegetable life it takes the form of chlorophyll, and as such is altogether dependent for its origin and existence upon the influence of solar light. Shut off from such influence, this element fails to produce itself, and vegetable tissues remain white, as instanced in the artificial cultivation of seakale and other culinary herbs. Prolonged isolation from such light, however, results in the arrest of the vital functions, and this circumstance fully explains the absence of chlorophyll producing vegetation below that depth in the ocean to which solar rays have access.[1] Green again, is not a simple colour, but a combination of two others—blue and yellow. May not therefore its origin be remotely related to the effect of the solar rays, technically white and colourless, but yellow to the external senses as represented by ordinary sunshine and upon the artist's canvas, acting in concert with the blue ether of which our outer atmosphere is composed?

Given this initial colour green, the three primary hues of nature follow as a necessary consequence:—Blue and yellow by the resolution of the initial factor into its constituent parts, and red as its direct or reflex product in abeyance to the law of polarity. That this latter law exerts a considerable influence in the origin and distribution of those glorious tints of nature which may be said to constitute its most potent charm, will scarcely fail to recommend itself to the attention of those specially conversant with the physics of colour, and in whose hands this subject may prove susceptible of important development.

W. SAVILLE KENT

[1] Reference may be appropriately made here to the predominant colour of fixed deep-sea organisms, such as sponges and corals. In the hexactinellid sponge-form *Phæronema* (*Holtenia*) characteristic of abyssal depths, the colour, as observed by the writer in association with examples procured from a depth of from five to six hundred fathoms off the coast of Portugal, and in connection with the dredging expedition of Mr. Marshall Hall's yacht the *Norna* recently referred to, was the most brilliant orange. This hue was likewise observed to be characteristic of the soft parts of the large deep-water branching coral *Dendrophyllia ramea* obtained in the same expedition. It will at once occur that this colour, orange, is directly complementary or polar to that of the superincumbent mass of water, always distinguished when overlying such profundities by its deep cerulean hue.

ELECTRIC DISCHARGE IN GASES

I.

IN a paper read some time since at the Royal Society,[1] Drs. Warren De La Rue and Hugo W. Müller gave the first part of an account of their researches on the electric discharge in gases. This part, of which we shall at present give some account, consists mainly of a discription of the apparatus employed in this research, and of the results of their experiments with gases at atmospheric pressure and pressures down to 141 millimetres. They have since communicated to the Royal Society a second part, which treats of the discharge in highly rarefied gases (vacuum tubes).

The source of electrification used by Messrs. De La Rue and Müller was a battery of chloride of silver elements; commencing with 1,000, the authors have from time to time increased the number of cells to 11,000 joined in series (11,330 volts). In spite of its containing a somewhat costly material, this element, when compared with the many other forms of voltaic cell at present in use, possesses points of advantage such as render its general adoption extremely probable; we therefore transcribe in considerable detail the authors' description of it in its present improved form.

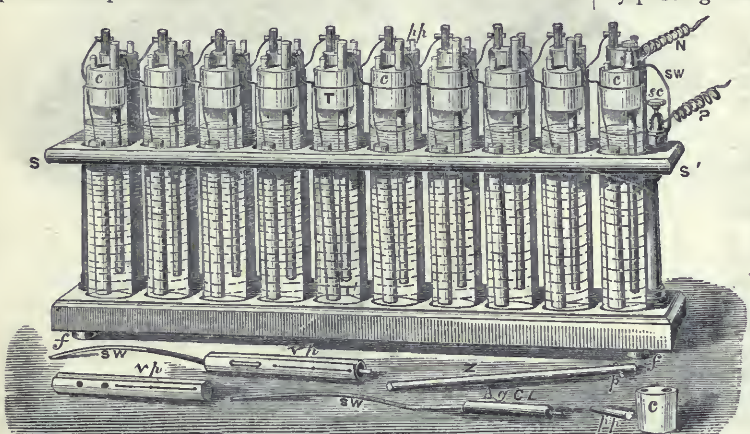

FIG. 1.—Nest of Cells.

Fig. 1 shows a nest of twenty cells of the most recent construction; the several components of the cells are given separately at the base of the stand. The glass tube T is $5\frac{1}{2}$ inches high, and $1\frac{1}{2}$ inch in diameter: it has a flat bottom. The stopper *c* is of paraffin, and is perforated with two holes, one for the zinc rod (*z*) to pass through, the other for letting in the liquid; the latter is ultimately closed with a paraffin plug (*pp*). Cork and india-rubber stoppers were tried and abandoned. The zinc is obtained of the Belgian Vieille Montagne Company. When it is intended to keep a battery more than a year in action the zincs should not be amalgamated, as the silver wires in contact with them would gradually be rotted through. Platinum, which would not become amalgamated, might have been substituted for the silver wires; but it would have cost 55*l*. extra per 1,000 cells. The zinc rods are 15 cm. long, 0·56 cm. in diameter, and perforated at the top with a hole 0·25 cm. in diameter. The chloride of silver (AgCl) is cast in the form of a rod on a flattened silver wire S W; the rods are 5·4 cm. long, 0·762 cm. in diameter, and weigh 12·97 grms. The silver wires are 20 cm. long, 0·127 cm. wide, and 0·0229 cm. thick, weighing 0·88 gms. each; they protrude slightly beyond the bottom of the rod of chloride, as will be seen from the figure. The wires and rods were obtained from Messrs. Johnson and Matthey, of Hatton Garden; the cost, including labour of casting, amounted to 2*s*. per cell. *v p* is a cylinder of three folds of vegetable parchment; at its lower end the folds are stitched together with thread, and at the upper part they are interlaced with the silver wire, and thus prevented from unfurling. The object of the parchment cylinder is to prevent the reduction of the chloride of silver rod, which would result from its accidental contact with the zinc. By giving proper bends to the silver wire before making up the cell it is easy to cause the chloride rod to lie vertically and press gently against the glass wall.

The liquid used for the cells is a solution of chloride of ammonium, 23 gms. to 1 litre of distilled water; by making use of a glass siphon with a long arm of india-rubber tubing, provided with a pinch cock, and terminating in a glass tube drawn down to enter freely into the hole in the paraffin stopper, it was found that 2,400 cells could be charged by one person in ten hours.

In making up a battery the glass cells are first arranged in their nests; next the paraffin stoppers are fitted with zincs; then the chloride rods are inserted and the cell closed with the stopper, the thin silver wire passing between the glass and the paraffin. When these operations have been performed for all, the cells are joined up by passing the silver wire of each cell through the hole in the zinc rod of its neighbour, and securing it there by pressing in a taper brass plug *p* with a pair of pliers. Ultimately, the cells having been charged with fluid, as already described, and closed by the insertion of *p p*, a hot iron is run round the outside of the stopper and round the zinc rod to secure the latter in its place, and make tight the joints by the melting and re-setting of a little paraffin.

Thus set up, the battery has an electromotive force of about 1·03 volt and internal resistance of not more than 5 ohms per cell: the former remains remarkably constant, but the latter increases, especially in cells that are left long idle. This rise in internal resistance is caused by a skin of oxychloride of zinc, which gradually forms on the zincs in all batteries where the zincs are immersed in a neutral chlorine compound. The battery may be restored to its original resistance by removing and scraping the zinc rods, but a more expeditious mode is to withdraw the small paraffin plug used to close the hole in the stopper through which the cells are charged, and to introduce into each cell, containing 50 c.c., 1 c.c. of pure hydrochloric acid, sp. gr. 1·16, containing 31·8 per cent. HCl gas, equivalent to 0·3689 gm. acid. Before introducing it into the cells, as is conveniently done by means of a graduated pipette furnished with a stop-cock, it is better to dilute the acid with an equal volume of distilled water. An effervescence takes place, and it is therefore necessary to allow the tubes to remain open twenty-four hours before the small paraffin plug is replaced, in order to permit the hydrogen, which is generated, to escape. It required two days for one person to perform this operation on a battery of 1,200 cells. The acid dissolves 0·3295 gm. of zinc or its equivalent of oxide.

After having been in almost daily use on circuits comparable with those occurring in overland telegraphy, it was found that in two batteries the amount of AgCl reduced in sixteen months averaged 4·57 gms. per cell, while in two other batteries which had been worked for ten months the reduction amounted to 3·57 gms. per cell.

An accident enabled the authors to give precise information as to the loss in working up the reduced silver; 600 cells having been accidentally allowed to run

[1] *Phil. Trans.*, clxix. pp. 55-122.

down, the loss in extracting and fusing the silver was 1·38 per cent.

Chloride of silver is charged at three-quarters of the price of silver; and the allowance made by Messrs. Johnson and Matthey for returned silver is about 6 per cent. less than the price at which they sell it. The charge for fusing and casting the chloride is 1*d.* per rod. Hence it appears that though the prime outlay is considerable, the cost of renewal is small, and a battery of these elements represents a certain amount of capital which might be realised at any moment. The labour required for setting up this battery is comparatively very little, and, this done, the element, from the insolubility of one of its electrolytes, is capable of standing idle for any length of time without other detriment than increase of internal resistance; this increase, too, occurs but slowly, many months elapsing before it rises from, say, 5 to 20 or 30 ohms per cell. Moreover, the element is notably clean and compact—a case 141 cms. high, 107 cms. wide, and 43 cms. deep, will hold 1,200. The details carefully given by Messrs. De La Rue and Müller of their very great experience of this valuable cell will probably be hailed as a boon by the many who have occasion to make use of voltaic batteries.

The accompanying diagrams show some of the apparatus which were specially devised by the authors to meet the insulation requirements of the high electromotive force they employed.

For instance, the ordinary form of double-reversing-key could not be used with this great battery, in consequence of the formation of an arc when the key is raised with the object of breaking the circuit. Figs. 2 and 3 show the new form devised by the authors. H is the handle fixed to the ebonite axis, which has metallic collars A Z at its extremities; these are connected to the springs S S′ by wires inserted in the axis. The battery wires are led to A and Z. The standards B and B, B′ and B′, are respectively connected by *diagonal* wires between the ebonite plates E and E′. Fig. 3 shows the open circuit position. In Fig. 2 the zinc pole is connected through S to B′ and the leading wire N′; the silver pole being similarly connected to P′. If now the handle H be thrown over to the right-hand side of the Fig. 2, Z will be connected to B on the right side, thence through the diagonal wire to B on the left side of the figure, and to P′, while A*g* will be similarly connected to N′. In this key, on breaking contact, the arms S S′ can be removed from the standards B B′ by a distance greater than that to which the arc can be drawn out.

Fig. 4 shows the micrometer discharger, by means of which the authors are able to measure the length of the spark to within $\frac{1}{10000}$ of an inch. Its construction is sufficiently obvious; it need only be remarked that the nut fixed in the cross-head at the top of the frame through which the screw works is in metallic communication with the clamp C, and is divided horizontally into two parts, which are pressed asunder by three spiral springs in order to prevent shake or play of the micrometer screw.

For special experiments it was necessary to design and have constructed a commutator capable of reversing the current many times in a second; that shown in Fig. 5 represents the most convenient form; it is capable of reversing the current 352 times in a second when the handle is turned 240 times in a minute. It will be seen that each revolution of A, B, C, D reverses twice. The figure is so distinct as scarcely to require any description; B and D are of one piece of metal, and also A and C of another, the spring conductors making contact at 90° distance from each other; each of the uprights supporting the axis of the revolving disc is in metallic connection with its respective insulated clamp. In the position shown in the figure the positive current passes from A*g* to the upright supporting the axis of the revolving disc, and through the right hand spring to the wire plate A*g*′; the negative current from Z to the upright on the other side of the revolving disc, only partly seen, thence through the upper spring to Z′.

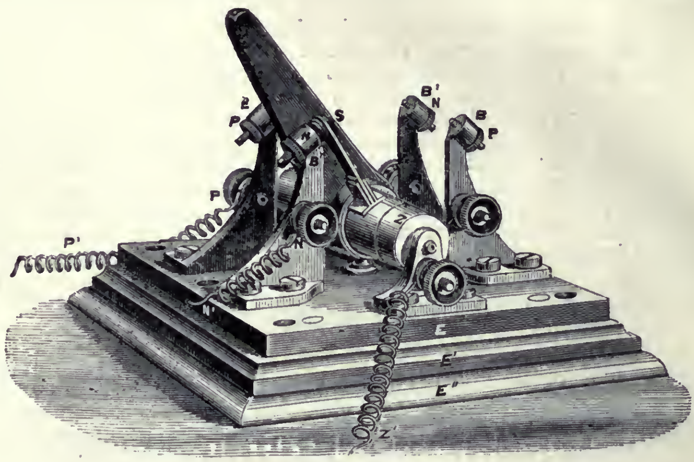

FIG. 2.

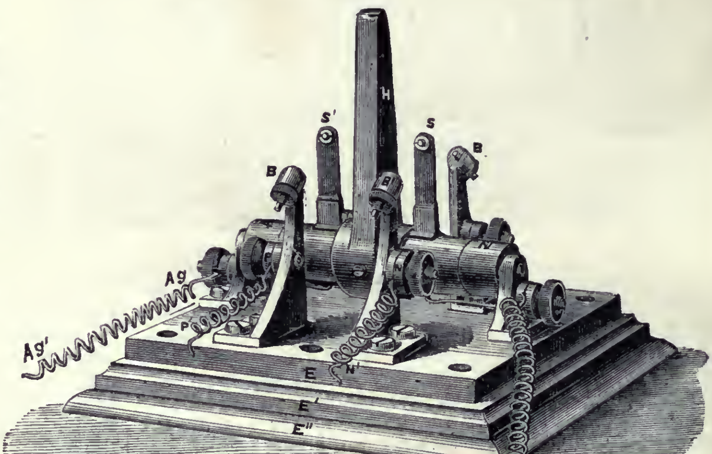

FIG. 3.

FIGS. 2 and 3.—Double Reversing Key.

Besides this, the authors had a contact breaker very similar in appearance, and shown *in situ* in Fig. 7 on the top of the dwarf cabinet of battery No. 1, containing 1,080 powder-cells; this cabinet top is of ebonite, and forms their ordinary working bench. M M′ represents a revolving mirror, which has a multiplying wheel, and in which the reflection of the discharge in a vacuum tube can be seen. In the circuit was a set of coil-resistances from 1 to 1,000,000 ohms, specially insulated, the wires running in grooves on insulating cylinders made of paraffined cardboard, in order that they may be kept at a distance; besides this set of resistances there were four

tubes of liquid having a maximum resistance of about 2, 4, 6, and 33 megohms respectively; all but one were furnished with adjustable wires by which their resistance could be diminished; two are charged with equal parts of water and glycerine, two with distilled water; each has a plug to throw the resistance out of circuit.

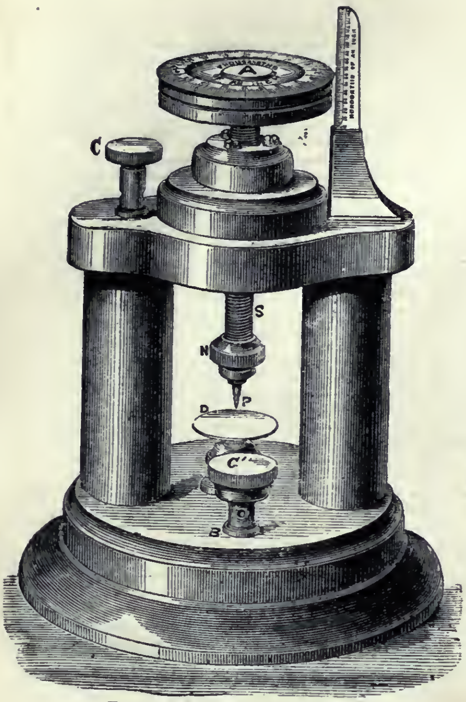

FIG. 4.—Micrometer Discharger.

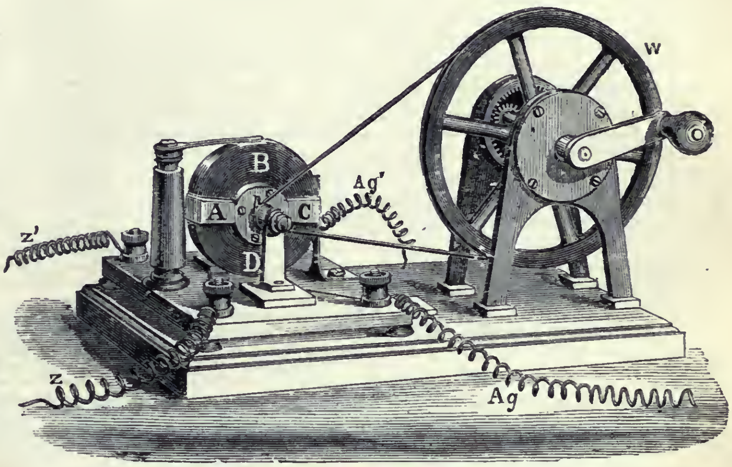

FIG. 5.—Rotating Commutator.

These resistances gradually diminish by the absorption of ammoniacal salts from the atmosphere, and this necessitates occasionally the entire renewal of the fluid.

As has been already stated, the paper deals principally with the discharge in gases at atmospheric pressure. Very elaborate series of measurements were made of the

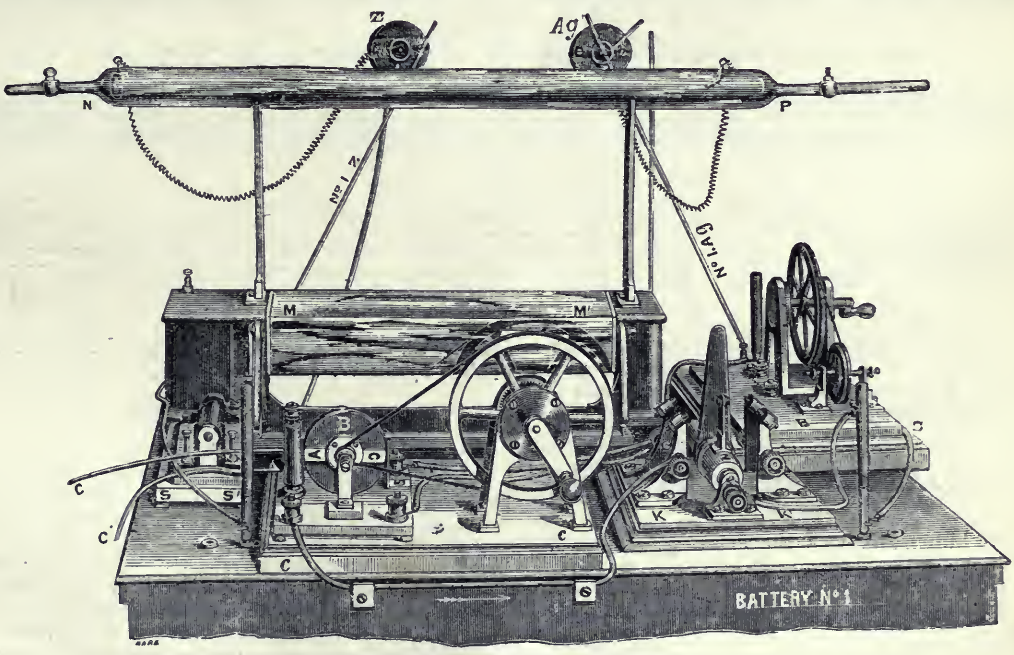

FIG. 6.—Table with Apparatus *in situ.*

potentials (*i.e.*, differences of potential) requisite to produce discharge at various distances between (1) plane surfaces, (2) spherical surfaces of 3-inch radius of curvature, (3) concentric cylinders, the diameter of the outer being constantly 0·4895 inch, that of the inner being varied from 0·4733 inch to 0·2865 inch, (4) a paraboloidal point and a

disc, (5) paraboloidal points. The results of each series are clearly set forth in the tables and plates which accompany the original memoir; here we have only space for a diagram (Fig. 7) giving a comparative view of the mean curves of all the measurements.

An inspection of the diagram will show that with plane

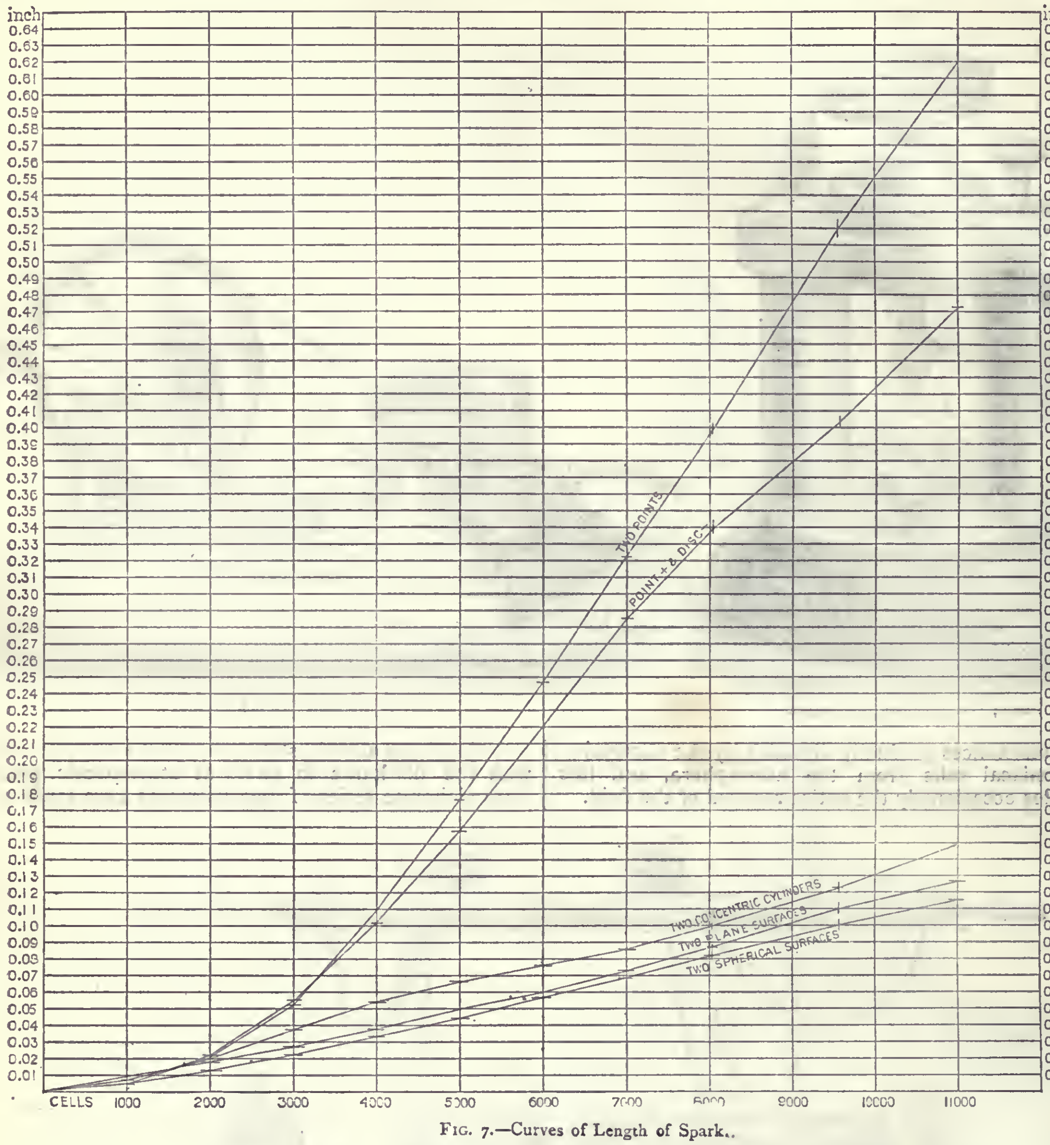

Fig. 7.—Curves of Length of Spark.

or slightly convex surfaces the potentials necessary to produce discharge at various distances are not proportional to the distances when these are small (less than 0·025 inch), but tend to become so as the distances are increased. These results confirm and extend those published by Sir W. Thomson.[1]

PHYSICS IN PHOTOGRAPHY[1]

II.

We have hitherto treated the question of a sensitive compound from what may be called a chemist's point of view, but it has also its physical aspect, and to enable us to understand what has recently been done in photography this latter must be briefly touched upon. To commence with, we are met with a difficulty in nomenclature which ought not to exist. Unhappily chemists and physicists employ the term molecule in a different sense. The physicist's molecule, for instance, in one place is defined[2] as "a small mass of matter the parts of which do not part company during the excursions which it makes when the body to which it belongs is hot." To avoid misapprehension the expression molecular group will be used for the physicist's molecule for want of a better, the word particle being rather too indefinite, and being usually applied to a group of molecules of visible size, a state of aggregation which is by no means necessary. The question as to the possible variation of the number of molecules composing a molecular group has not been entered into, as it would be trenching on ground

[1] Continued from p. 491.

[2] "Theory of Heat," Maxwell.

which has been explored by others in relation to a different subject; but this may be stated as a matter of observation that some compounds of silver which are sensitive to light are capable of forming two molecular groups, one of which absorbs the blue rays, and the other the red rays.

The iodide and bromide are the salts of silver which, either separately or together, are chiefly employed for securing a developable photographic image; and it is these with which we shall principally deal, though the chloride and one or two other combinations will come under review when considering certain new phases in photography. The point to which attention must now be directed are the radiations to which these compounds are sensitive; and these are evidently dependent upon the absorption that takes place in them individually. If we take precipitated silver bromide and fuse it into a crystalline mass, and examine it spectroscopically, we find that it energetically absorbs all rays from the extreme violet to the green, and also less markedly in the yellow of the spectrum; whilst if we place a slab of it before the slit of the spectroscope, and photograph the spectrum of white light passing through it, we find that it completely cuts off the ultra-violet rays; so that we may say that the red and perhaps the ultra-red rays are the parts of the spectrum in which but slight absorption takes place. Now, since absorption means work done in the absorbing body, it is evident that we may expect some action to take place in the silver bromide when exposed to these rays; and the action may be a chemical change, or a rise in temperature, it being remembered that the latter may co-exist with the former, since it may be produced by the result of chemical action as well as by the absorption of the radiation. The question then arises, On what does the possibility of a chemical change in a compound depend? This is a question which is very easily asked but not so easily answered. It must evidently depend amongst other things on the capability of the molecules of the compound to throw off some atom or atoms ; or on their capability of acquiring some vibrating atom or atoms of a body with which they may be brought in contact; in other words, that the molecule shall be in a state verging on indifferent equilibrium, and seeking rearrangement of the atoms when the impulses of the waves forming the radiations impinge against it. Taking for granted that the chemical theory of the formation of the photographic image holds good, we know that the atom of the halogen is thrown off from the molecule of the silver compound, leaving behind two atoms of the metal combined with one atom of the halogen. Thus silver bromide (Ag_2Br_2) is split up into argentous bromide (Ag_2Br) and bromine. If a film of the yellow sensitive salt be exposed to the spectrum an image is developed on all the parts which it absorbs, in other words, absorption in this case means chemical action. Similarly with the iodide where the absorption of radiation is most energetic there we have a chemical change. With the chloride we have a different phenomenon ; crystalline chloride is nearly colourless, and the absorption of every part (though not necessarily of the invisible regions) of the spectrum must be nearly equal, but we find that this salt is sensitive only to about the same radiations, under ordinary conditions, as the iodide. An explanation of this will be offered at a more advanced stage of these articles, but it may be as well to note the fact now. In the accompanying diagram the ordinary results of the exposure of the three chief silver compounds to the spectrum are shown (Fig. 2).

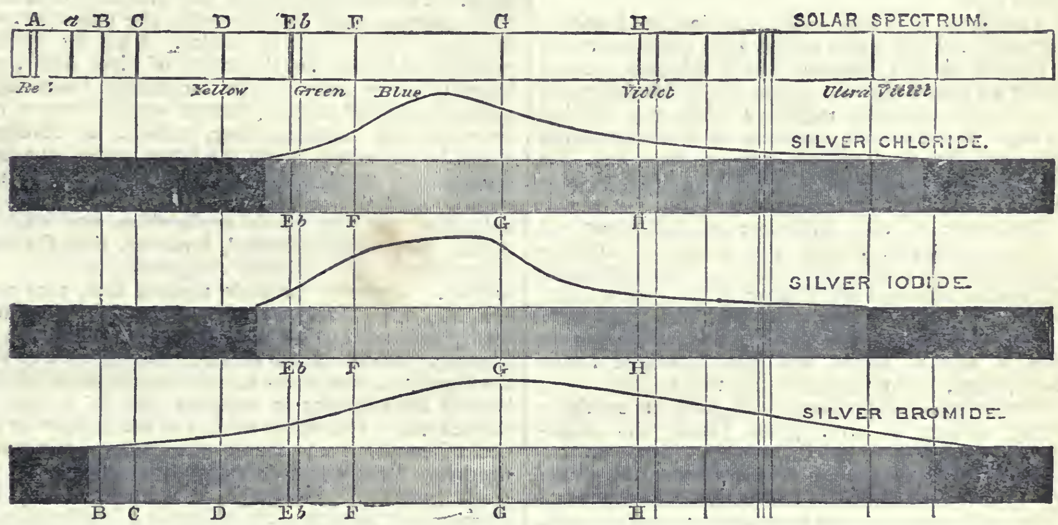

FIG. 2.

When we obtain a molecular grouping in which the red is absorbed, we may expect that the same chemical change may take place as when in the former state. This is not a necessity, since, instead of a reduction to a less complex form of molecule, the new compound, formed by the aid of light, might be rendered more complex by annexing other foreign atoms. An example of this we have in Hunt's experiment, already quoted; where it is evident that the violet subchloride would be sensitive to light if it were proved that light alone caused the absorption of oxygen. Again, in the combination of chlorine and hydrogen, when exposed to light, we probably have a greater complexity of molecular structure introduced.

In the ordinary state in which silver bromide is formed in a collodion film (we will take this compound as it is this one which has been principally examined), we have it in the state in which the blue is absorbed and the red transmitted; but there are means by which it may be made to absorb the red. We may obtain the bromide in either state by what is known as the "*emulsion process.*" Briefly, this process may be described as one in which an emulsion of silver bromide is formed in a viscous liquid, such as collodion or a solution of gelatine, by first dissolving a soluble bromide in it and then adding to it a solution of silver nitrate. The particles of solid bromide thus formed remain suspended in the fluid. In the emulsion with collodion we can get the silver bromide in various states according to the rapidity with which we add the silver nitrate. Thus if we add it rapidly, we get a mass of silver bromide which

is coarse and has a tendency to subside, and which, when poured upon a glass plate and dried, gives a film transmitting white light; whilst if we add it drop by drop and shake it up between each addition, we find that the bromide remains suspended for days, and that a film of it transmits orange light. If we take the emulsion, however, as first described, and place it in a still, and bring it to a state of ebullition, distilling over the ether and alcohol solvents of the collodion, thus breaking up the heavy particles of the suspended bromide, and then wash the contents of the flask in water to get rid of all soluble salts (which must necessarily exist owing to the double decomposition of the soluble bromide and the silver nitrate), we shall find, on redissolving the mass, after washing with alcohol, that the film will transmit lavender or a sky-blue light. On the other hand if the solvents from the emulsion which transmits the orange light be allowed to evaporate spontaneously and the solid residue be then washed and redissolved, the film will still transmit red light. It will thus be seen that silver bromide may be secured in two states *in one of which it principally absorbs the blue and in the other the red.* The chances are that the former is sensitive to the less refrangible rays of the spectrum, whilst the other is only sensitive to the more refrangible rays.

The emulsions, if made exactly as described above, might or might not give a film which, after exposure to the image formed in the camera, would develop without blackening all over under the action of the developer, or, in photographic parlance, might or might not develop without fog. If the soluble bromide be in excess in the emulsion, and be then washed out as described, the sensitive films would be free from this evil, whereas if the silver nitrate were in excess, this would not be the case. The cause of this difference in behaviour has lately been explained, though the means of correcting the emulsion has long been known. The reasoning will perhaps be rendered more clear if the experimental proofs be recounted in the order in which they were made. We must suppose that we have at hand a perfect emulsion, a film of which will give a bright image on development, after exposure in the camera. Let half-a-dozen plates be prepared with such an emulsion by simply flowing it over glass plates and allowing the films to dry; and then let these be exposed in the camera for the time necessary to give a strong image on development. Let the plates be immersed respectively after exposure in a weak solution of nitric acid, of potassium permanganate, potassium bichromate, nitrous acid, hydroxyl, iodine or bromine vapour, or be exposed to the action of ozone, it will be found that the image impressed by light will steadily refuse to develop, however much it may be coaxed; or again, if another half-dozen plates be prepared and be exposed to light external to the camera, we know if exposed to the lenticular image after such treatment, that we might obtain an image on development, but that it would be obliterated by the veil induced by the preliminary exposure. If between the preliminary exposure and exposure in the camera the plates be treated with any of the above solutions or vapours, and be then washed, we should find the impressions of light in the camera would yield images perfectly free from the veil. In other words the treatment of the film with any of these solutions will destroy the effect of the action of light. Now as we have already shown, the image is formed of silver sub-bromide; hence we may say that the treatment has changed the sub-bromide to an undevelopable compound. When exposed to iodine or bromine the sub-salt will naturally become converted into the primitive salt, but when we look at the nature of the other destructives, we cannot but be struck with the fact that they are either solvents of metallic silver or oxidising agents. In the first case we may presume that the loose atom of the silver of the sub-bromide (Ag_2Br) is dissolved away and converted into some other form of silver, leaving behind the half molecule of bromide, and in the other we may presume that the sub-bromide is oxidised to form an oxy-bromide of silver.

With this fact as a starting-point, it appeared probable that the elimination of a veil due to an emulsion ought to be effected by the same agents as if the veil occurred through the action of light. It was well known that in order to get an emulsion perfectly free from this enemy that chlorine, bromine, iodine, or some diad chloride or bromide were necessary to be added to the washed emulsion if the silver nitrate were in excess at first, and that nitric acid had the same effect if added to the emulsion with the silver nitrate. Here, then, seemed to be the proof of what was wanted, but another link was still required to make the reasoning complete. In making an emulsion if the soluble bromide was in excess none of these agencies were required. The question then arose as to why this was the case. To clear this up a fair hypothesis was taken, viz., that no soluble bromide was absolutely free from contamination. If the bromide were of the alkalis or some of the metals such as zinc, it was probably contaminated with the oxide, whilst with other diad metals it was probably of the lower form of bromide. Thus cupric bromide was probably contaminated with cuprous, and cobaltic with the cobaltous, though in infinitesimally small quantities. Now the former impurity would cause the formation of silver oxide, and the latter of silver sub-bromide (argentous bromide). Experiment showed that the former would act as a nucleus on which the metallic silver, reduced by development, would be deposited, whilst the latter would have the same composition as the latent image and thus induce the objectionable veil. The same reasoning applied to the chlorides, but the whole explanation was still incomplete. Experiment showed, however, that the order of formation of the different compounds of silver was as follows. Argentic bromide formed first, next argentic chloride, then argentous bromide and chloride, and finally the oxide. If, then, there was but little of the impurity present in the soluble bromide used in forming the emulsion, pure silver bromide would alone be formed, leaving the impurity in solution and in a state to be washed out. The whole subject of the fog-giving properties of emulsion was thus cleared up, and the correction necessary for it was apparent.

All practical photographers are aware that in the ordinary dry plate processes there is a deterioration of the image if plates be kept a long time before exposure and development, and if sufficiently long time elapse that the image will almost refuse to develop at all. The question arises why this obliteration of a developable photographic image takes place? We have seen how an image can be destroyed artificially by the use of oxidising agents, and we might naturally infer that the same destructive agency might obliterate the image even when the oxidising agent is merely ordinary air, and after considerable experimental proof we are compelled to come to the conclusion that this is the case, more especially when it is found that any readily oxidisible matter, such as gallic acid, if applied in solution and dried in contact with the sensitive film, preserves the image for a longer period than if this precaution be omitted. The oxidisable matter has to be oxidised before the image itself is attacked, for we may assume that the image itself is not as readily oxidisable as such bodies as that mentioned, and many others. The fact that the image can be oxidised and thus destroyed, seems to disprove the once held opinion that the undeveloped image was formed of metallic silver, a body which will tarnish but not oxidise, the pure oxides being unstable.

As a sequence to the destruction of the photographic image by oxidation, the hitherto unexplained results which Draper obtained when photographing the spectrum
